A relatively new addition to accelerate sample dissolution and digestion is the microwave oven. A number of such ovens are specifically designed for chemical sample digestions with heating compartments lined with relatively inert materials and a means to remove corrosive vapors. Their power levels are far more precisely controlled than those of household microwave ovens, and monitors of the sample temperatures and pressures are provided. Gram-size samples can be heated to a given temperature from 10 to 100 times faster than by conventional thermal heating and with far better control of the speed of heating and the temperature. Microwave assistance also facilitates digestions in sealed containers. These containers are most often made of a type of Teflon^{TM} called (perfluoroalkoxy)ethylene (or Teflon PFA). Digestion in closed containers obviously is a superior way to ensure that analyses will be accurate and precise, since the loss of analyte is limited and introduction of interferents is easier to avoid. Both characteristics are especially important in trace and ultratrace analyses. In addition, the closed containers allow digestion to be accelerated since the boiling point can rise above the normal boiling point of the acid at atmospheric pressure. As an example, concentrated (constant boiling) nitric acid boils in an open container (at 1 atmosphere pressure) at 120.5 °C, while in a microwave pressure vessel, the temperature can be held at about 185 °C. A typical digestion reaction could be accelerated about 800-fold with this temperature difference. The limits of microwave digestion arise from the pressure and temperature limits of the containers and the electrical and chemical properties of the samples.

14.1
Introduction

The cyclotron was invented in 1931, and from its inception to the 1960s installations were designed chiefly for research in nuclear physics and radiochemistry. Several laboratories developed strong affiliated programs in nuclear medicine, radiation oncology, and materials science, and these became the primary functions of some laboratories during the 1960s. Since then, more cyclotrons have been built for research purpose in nonnuclear fields and for industrial and medical applications. This scenario has been described in Chapter 13. That chapter mainly describes the history of cyclotrons and their design features in some detail, while this chapter introduces new fields of application, some speculative, and gives illustrations of recent activity in some older fields. It describes some new cyclotron technology and discusses the factors that may limit the intensity of the beam from cyclotrons.

An overview of the field can be found in the Proceedings of the 14th Conference on Cyclotrons and their Applications (Cornell, 1996). In the year 1998, there were more than 130 cyclotrons operating commercially and about 75 more in research institutions. Approximately 30 projects involving new machines or major expansions of existing facilities were under way.

14.2
Applications of Cyclotrons

14.2.1
Cyclotrons as Sources of Neutrons

It is becoming harder to convince the public to commission new reactors or to replace older ones. Accelerators are being perceived as a safer source of neutrons for the production of power by nuclear fission and for other traditional reactor applications. They function by directing an ion beam onto a target with a high atomic number. Spallation reactions, and sometimes fission reactions, produce a copious number of secondary particles including fast neutrons. These final products (neutrons) may then be slowed down in a moderator to give the velocity spectrum suited for the application. The optical source of the neutrons is less diffusible than in a reactor and much less total power is dissipated.

Examples of spallation neutron sources are ISIS at the Rutherford-Appleton Laboratory, near Oxford, United Kingdom, and LANSCE at the Los Alamos National Laboratory, New Mexico. ISIS is based on a 200-μA, 800-MeV proton synchrotron and

LANCSE on a linac and storage ring handling 100-μA, 800-MeV protons. The nature of operation of these types of accelerator is to produce neutrons with a pulsed time structure that can be useful for time-of-flight spectroscopy. The most powerful cyclotron proton beam at present is that at the Paul Scherrer Institute (PSI), Villigen, Switzerland, where 850 μA of the 1.5 mA of 590-MeV protons is extracted from the continuous wave PSI cyclotron is directed toward the SINQ cold neutron source to produce $10^{14}\, n\, \mathrm{s}^{-1}\, \mathrm{cm}^{-2}$; this is comparable to a medium-flux reactor. Liquid-deuterium moderators can be placed near the maximum neutron flux, and the continuous beam of very cold, 25-K or 2-meV, neutrons will match that of the current best source, the reactor at the Institut Laue-Langevin (ILL), Grenoble, France.

Physicists, chemists, and biologists use neutron beams to elucidate complicated molecular structures. Neutron therapy and neutron radiography are the other established applications that use beam from cyclotrons with $k = 40$–70. Two newly proposed applications are described below. Neutron sources based on cyclotrons have the advantage that they are smaller and more economical to operate than those using linacs or synchrotrons, although linacs may eventually produce more beam power.

14.2.1.1 Radioisotope Production by Neutrons

The most widely used medical radioisotope is $^{99\mathrm{m}}$Tc with millions of diagnoses done per year using this isotope. Because it has a 6-hour half-life, it is supplied in the form of a generator using a ^{99}Mo parent having 66-hour half-life. This isotope is obtained from reactors as the fission by-product of ^{235}U. There have been proposals to make $^{99\mathrm{m}}$Tc or ^{99}Mo by the proton bombardment of an enriched ^{100}Mo target; however, technetium produced directly would have to be used within few hours of production, and there may be difficulties in separating ^{99}Mo from the ^{100}Mo target. Ion Beam Applications (IBA), Louvain, Belgium, has proposed a facility to make ^{99}Mo by fission, as at present, but to create the neutrons by bombarding a lead target with a 1.5-mA beam of 150-MeV protons. Approximately one fast neutron would be produced per each proton. The target would be surrounded by a water moderator that would contain the secondary production targets of ^{235}U and would thermalize the neutrons. The system would operate safely below the critical level and the calculated flux of $2 \times 10^{14}\, n\, \mathrm{cm}^{-2}\, \mathrm{s}^{-1}$ should produce 2×10^{14} Bq per week of ^{99}Mo, which if efficiently extracted and distributed would match the world's demand.

14.2.1.2 Production of Thermal or Electrical Power

In the so-called energy amplifier (Rubbia, Mandrillon and Fietier, 1994), a beam from an accelerator would initiate a fission cascade in a target placed inside a calorimeter. The fission products would be slowed down in the calorimeter and their energy would be transformed into heat. Electrical energy transformed in turn from heat would exceed that required to operate the facility and the excess, as electricity or heat, could be delivered to external users. Thorium is proposed as the target; it is more abundant than uranium, fissile isotopes can be ‘‘bred’’ from it through nuclear interactions, and its use would result in a smaller amount of radioactive waste. Such ideas have been proposed before but the required technology seems closer now.

A schematic energy-generating complex is illustrated in Figure 14.1. In this proposal (Fiétier, Mandrillon and Rubbia, 1996),

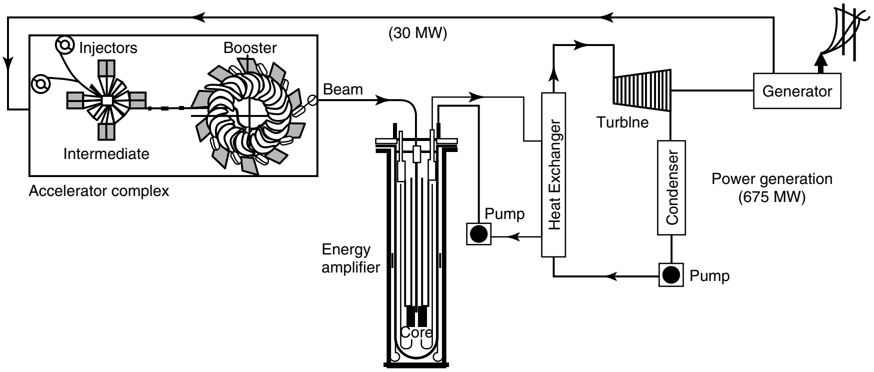

Fig. 14.1 The major components of an energy-producing complex. The cyclotron chain consumes 30 MW to produce 12 MW of 1-GeV protons. These initiate fission reactions in the core of the energy amplifier. About 1500 MW of thermal energy would be produced, which could be transformed to 675 MW of electrical energy. (Courtesy of P. Mandrillon, Cyclotron Laboratory, Nice, France).

two injector cyclotrons deliver 6 mA of 10-MeV H^- ions, and two separated-sector cyclotrons accelerate a combined 12 mA of protons first to 120 MeV and then to 1 GeV, for injection into an amplifier module. Interestingly, one 10-MeV beam would be extracted by stripping and the other using a deflector channel; the two would be overlapped in the injection line to reduce space-charge forces. Each amplifier module would produce 1500 MW_{TH}, of which 30 MW would be returned to operate the accelerators. The neutron flux in the target would be in the range of $10^{14}\ cm^{-2}\ s^{-1}$, well below criticality so that energy production will stop when the incident beam of protons is shut off, thus offering an extra measure of safety. A plant might consist of several such generators in parallel.

14.2.2
Production of Radioactive Ion Beams (RIBs)

Nuclear physicists have used separated isotopes in their targets and ion sources for several years; the isotopes could be unstable provided half-lives were reasonably long. The current interest is in the production on line of isotopes with short half-lives (minutes or less) and energies varying from $\sim$1 keV amu^{-1} to many MeV amu^{-1}. Nuclear physicists are interested in the structure of nuclei far from the line of stability in the mass (A)–nuclear charge (Z) diagram. Astrophysicists as well as nuclear physicists are interested in the reaction mechanisms of these nuclei, because they can be part of the chain of reactions that breed heavy elements in stars. Some experiments with the less easily produced isotopes can be performed by confining them in neutral-atom traps. Ions are neutralized by first implanting the beam in a surface and then re-evaporating them as atoms. These are cooled and confined by interchanging their momentum with crossed laser beams. The final ensemble may have the atomic shell structure elucidated by probing with lasers of different frequencies, and nuclear properties can be inferred from their effects on the atomic shells. Six thousand $^{38\mathrm{m}}$K atoms have been constrained to a volume of 2 mm^3 in such a trap; the half-life of the metastable isotope is about 1 second.

There are two principal methods to generate beams of short-lived isotopes. In the first method, an energetic beam is directed onto a thin target; the unstable ions are made by direct nuclear reactions and emerge with significant energy according to the laws of kinematics. They are captured in a large-acceptance beam-transport system and led to an experimental area. This method was used at the Bevalac high-energy synchrotron (now shut down) at Lawrence Berkeley Laboratory (LBL), California, and is presently employed using cyclotrons at Michigan State University (MSU), East Lansing, Michigan, and GANIL, Caen, France. Most new radioactive ion beam (RIB) facilities, including an upgrade at GANIL, will use a second method in which a high-power primary beam from an accelerator hits a thick target to produce both stable and unstable isotopes of many different species by spallation reactions. These continually diffuse out of the target, which is usually hot, into an ion source. Ions emerge at the source potential, and a mass separator selects the species of interest, which is then transported to an experimental area or to a second accelerator. Such an on-line isotope separator, ISOLDE, at CERN, Switzerland, has been producing unstable-ion beams of ~1 keV amu^{-1} for 20 years using first a proton beam from a synchrocyclotron and more recently a 1-μA, 1.2-GeV proton beam from a synchrotron. Isochronous cyclotrons offer a 10- to 100-fold increase in primary beam power and are the foundation of facilities under construction at TRIUMF at Vancouver, Canada, GANIL, INFN-LNS at Catania, Italy, and RIKEN at Saitama, Japan. One quite different proposal, PIAFE, would place the target and ion source, biased at 30 kV, within the pile of the reactor at ILL. Ions of the neutron-rich isotopes produced would be transported 400 m to the cyclotrons at the nearby Institut des Sciences Nucléaires for acceleration.

14.2.3
Ion Beams in Industrial and Materials Research

There are now two institutes dedicated to research on condensed matter that use beams from cyclotrons. These are the Hahn–Meitner Institute (HMI), Berlin, Germany, and the Institute for Advanced Materials (IAM), Ispra, Italy.

14.2.3.1 Thin-Layer Activation

The process of thin layer activation and its applications were discussed in Chapter 13. A recent example of its utility is the investigation of the spallation of the oxide scale that protects alloys from corrosion (Stroosnijder, 1996). This scale often has a different coefficient of thermal expansion from the underlying layer, and thermal cycles can cause cracks to appear and material to spall off. The conventional procedure for measuring resistance to corrosion involves subjecting a sample to several cycles of the industrial process and then measuring the change in mass. The difference in weight of the sample gives the amount of material loss, which may be only a small fraction of the sample mass. The amount of material spalled away can be measured much more accurately by first producing radioactivity in the surface layer by bombarding a specimen with a proton or deuteron beam, then subjecting the sample to cycling, and finally measuring the activity in the spalled material only.

IAM achieves a precision of nanograms per square centimeter. One may choose to irradiate only a part of a sample; for example, one need not irradiate regions of high curvature in a scaled-down model because these will not exist in the full-scale item.

The radioisotope to be produced by the beam for thin-layer studies must have an activity that can be easily measured, usually γ rays. It must have a half-life matched to the duration of the tests and may have to interact chemically with the surface, for example, in the formation of an oxide scale. In some cases, no suitable isotope can be made, or the material may be damaged by the beams that produce them. A solution may be to implant radioactive ions directly. However, not every element has an isotope with a suitable half-life or γ activity, and the range of the heavier ions may be too short. ^{7}Be has been used at MSU and at the Kurchatov Institute, Russia, to irradiate ceramic, polyamid, or viton machine parts and to measure their rate of wear during the operation of the machines. There is a proposal at TRIUMF to measure the wear of hip joint replacements by implanting ^{7}Be, or possibly ^{22}Na.

14.2.3.2 **Constructive Processes in Materials**

Emerging evidences suggest that ion beams can cause constructive processes, that is, those that create order. Ion beams passing through matter cause electronic excitation, ionization, and displacement of atoms. These processes usually destroy molecules, but it is well known that electron beams can cause cross linking of molecules in plastics. Constructive processes involving ions appear as the energy density transferred to excitation and ionization increases (Fink *et al.*, 1994), and at sufficiently high energy densities, the constructive yield can surpass the destructive yield. The passage of a heavy ion produces a dense cloud of positive charges within a few nanometers of the track, and this cloud in turn is surrounded by a penumbra of knocked-on electrons that excite nearby atoms. The ion thus produces a transient pulse with a high energy in a small volume that quickly quenches once the ion has passed. Such a sequence is suitable for the synthesis of buckminsterfullerene. C_{60} has been found within the tracks of 5-MeV $^{6}Li^{+}$ in polyimide at HMI and of 130 MeV amu^{-1} $^{161}Dy^{22+}$ on pyrolytic graphite at the UNILAC Laboratory, Darmstadt, Germany. Other examples are given in Apel (1996).

14.2.3.3 **RIB Complementing Muon Spin Relaxation (μSR) Techniques**

Research laboratories have used muon beams to investigate solid state structure, magnetism, chemical reaction rates, and so on. Unstable heavy ions also can be used in these fields. Polarized beams of β emitters can be stopped in a layer of material of less than 10 nm thickness, the isotope precesses in a magnetic field, and the observation of the modulation of the decay rate by a β detector will yield information analogous to muon spin relaxation (μSR). The precision may be better than μSR for some of these cases, because the sample is thinner and because more precession cycles may be observed since β decay lifetimes are much longer than muon lifetimes.

14.2.4
Medical Applications

14.2.4.1 **Radioisotope Production by Ions**

The most popular accelerator for isotope production remains the variable-energy H-cyclotron with 0.1–1-mA beam and a

◀ **Fig. 14.2** (a) A portion of the H^- beam circulating in the TRIUMF cyclotron is stripped at 70 MeV, at approximately half of the maximum orbit radius. The protons curl out of the cyclotron into a beam line, which focuses and directs them into a shielded patient treatment area. (b) The equipment used to treat tumors of the eye at TRIUMF. The scatterer introduces a broad Gaussian distribution in the angular divergence of the 70-MeV proton beam extracted from the cyclotron. The collimators trim the sloping sides of this distribution and reduce the flux from the ~1 nA extracted to a treatment level of about 10^7 protons $\text{cm}^{-2}\,\text{sec}^{-1}$. The shape of the final collimator is matched to the tumor being treated. The material in the range shifter reduces the proton energy to match the distance to the rear of the tumor; the variable-thickness range modulator spreads the dose over the tumor depth. The ion chamber measures the dose of ionizing radiation delivered. The X-ray tube is inserted to confirm the tumor position with respect to the proton beam line. (Courtesy of E. Blackmore, TRIUMF, Canada).

maximum energy in the range 18–30 MeV; over 100 of these have been installed in the last decade. They are economic and reliable in operation and have a high beam power for relatively low capital cost. The TRIUMF laboratory and Nordion Inc., Canada, have jointly demonstrated extracted beams of 30 kW of 30-MeV protons. Also their small size requires a smaller volume of shielding than some competing accelerators. Nine very small 12-MeV H-superconducting OSCAR cyclotrons have been sold by Oxford Instruments Corp., United Kingdom.

Other continuing developments include the production of generators to supply short-lived isotopes to institutions without production facilities. These generators are isotopes that decay into the short-lived species required for imaging and have a lifetime long compared with transportation times, for example, $Sr^{82}(25\ d) \rightarrow Rb^{82}$ (6 hours and 1 minute). There are also proposals to use focused beams of RIBs to accumulate high activities in a small volume.

14.2.4.2 **Proton Therapy**

The vast majority of medical treatments with particle beams are intended to destroy cancerous tissues while attempting to spare neighboring healthy tissues. Ion beams are well suited to this because they have a well-defined range (see Figure 13.15) and can be focused to spots in tissue within a diameter of a few millimeters. Proton beams have a lower magnetic rigidity than heavy-ion beams with the same range and thus the accelerator and beam-transport system will be smaller and cheaper. There are 19 proton irradiation facilities at present, and the number continues to increase.

The equipment for a 70-MeV beam to treat ocular melanoma is shown in Figure 14.2. Deeper tumors require higher particle energies. The 230-MeV protons would have sufficient range for most people but an accelerator may have to provide 250 MeV or even 270 MeV to compensate for energy lost in the beam-preparation system. Tumors with large area can be treated either by incorporating a second scatterer into the standard passive system illustrated in Figure 14.2(b) or by steering, usually termed *scanning*, a small-diameter beam over the tumor area. The second scatterer is designed to broaden the center of the Gaussian distribution produced by the first and to remove the penumbra. The scatterers absorb some of the beam energy and may produce a small background of secondary particles. Scanning techniques avoid these effects and are considered to match tumors of irregular shape better, but they are more complicated. Each scan treats a certain depth of tumor, and the energy of the beam entering the patient is changed to treat ''slices'' at different depths. The beam current must not vary by more than a few percent for scanning and must accommodate refinements such as synchronization with breathing. The beam from a cyclotron is well suited as it shows little modulation on a millisecond and longer timescale.

It can take an hour to change the energy of a beam from a variable-energy proton cyclotron. Consequently, the treatment facilities often operate with a fixed extraction energy and use energy-absorbing material followed by a magnetic momentum-selection system to obtain adequate energy for treatment. The radiation background and residual activity in the degrader and momentum collimator are acceptable. Both are well shielded, the beam currents used are $\leq 300\,\mathrm{nA}$, and the beam is usually switched on for less than 10% of the working day because much time is consumed for setting up the patients for treatment. Cyclotrons for therapy occupy a lesser space compared with most treatment rooms and are less expensive and easier than synchrotrons to build and operate. IBA have designed a compact 235-MeV proton cyclotron, beam-preparation system, and gantry specifically for therapy. The magnet of this cyclotron is not superconducting but it does operate with highly saturated iron; the hill field is 2.3 T and the outer diameter of the yoke is about 4.5 m. This results in a cyclotron of relatively small size without the necessity to provide a supply of liquid helium in a hospital. Two have been sold, the first to Massachusetts General Hospital, Boston, United States and the second to the National Cancer Center, Kishiwa, Japan.

14.2.4.3 Neutron Therapy

Salivary-gland and advanced prostate tumors are examples of the sites that respond best to direct irradiation by neutron beams, and there are perhaps 10 cyclotrons attached to hospitals performing such treatments. Boron-capture therapy is a new modality that incorporates ^{10}B into molecules that enter tumors easily; this is followed by irradiating the patient with neutrons. The reaction $^{10}\mathrm{B} + \mathrm{n} \rightarrow {}^{7}\mathrm{Li} + \alpha$ has a cross section of hundreds of barns for thermal neutrons, and the reaction products are highly ionizing and destructive over a short range. At present, trials are being carried out at reactors and hospitals such as The Department of Radiation Oncology, University of Washington, Seattle, that have cyclotrons that can produce 10^8 slow neutrons $\mathrm{s}^{-1}\,\mathrm{cm}^{-2}$ thermalized in the patient. Ideally about $10^9\,\mathrm{s}^{-1}\,\mathrm{cm}^{-2}$ thermal neutrons are required at the tumor, and if the method proves successful, an optimized cyclotron and neutron preparation system will be required for hospital use.

14.3
Advances in Cyclotron Design

14.3.1
The Separated-Orbit Cyclotron

A most innovative, but technically challenging, machine is the superconducting separated-orbit cyclotron (SOC) Tritron at Munich, Germany. It combines some of the features of a cyclotron and synchrotron. The typical isochronous fixed-frequency cyclotron with $\beta \approx r\omega/c$ accelerates a continuous stream of beam bunches but with a turn separation that unfortunately decreases as $(\beta\gamma^3)^{-1}$. Tritron is also isochronous, with a fixed field and accelerating frequency, but in addition, the turn separation is constant. For turn separation to be constant, the accelerating voltage should increase proportionately with radius. Ions in Tritron follow a fixed spiral path in the field of superconducting magnets, each turn occupying its own channel in the iron (Figure 14.3). Efficient superconducting radiofrequency (rf) accelerating cavities produce a radial turn separation of 40 mm, much larger than the beam width. Particles leading or lagging in phase with respect to the reference particle will deviate in energy and eventually in radius. The field gradient dB/dR in each separate channel can be chosen to provide a longitudinal (phase) restoring behavior as well as transverse focusing provided that the beam bunches lie at negative phases where $dT/d\phi > 0$ (Trinks, 1991). This characteristic resembles that of a synchrotron; it takes about four turns in Tritron to complete one synchrotron, or phase, oscillation. The existence of longitudinal focusing allows operation at 170 MHz with harmonic numbers $h = 14–55$, larger than the 1–10 typical of more conventional cyclotrons. All components are now in place and a beam of $^{32}S^{14}$ ions has been accelerated over several turns.

14.3.2
Injection from Radiofrequency Quadrupole Linacs

Linear accelerators usually operate with a fixed rf and a fixed particle-velocity profile, which results in a fixed output energy per nucleon (see Chapter 16). This is a limitation to their use as injectors to variable-frequency cyclotrons. Some years ago, a variable-frequency drift-tube linac, RILAC, was built at the RIKEN Laboratory, Saitama, Japan. The drift tubes were attached to the inner end of coaxial $\lambda/4$ lines, and the frequency was altered by varying the electrical length of these lines by means of a sliding short. These Wideröe-type linacs still require an injected beam of several hundredkilo electronvolts. Radiofrequency quadrupole (RFQ) linacs accept beams at a few keV amu^{-1}, bunch it, and accelerate it with high efficiency, but again they usually operate at a fixed frequency. Moreover their emittance is not well matched to a cyclotron acceptance. This situation is changing. A variable-energy and -frequency four-rod RFQ injector linac is being built by a group at Frankfurt University to match the dee frequencies, 80–110 MHz, of the $K = 134$ MeV separated-sector cyclotron at HMI. It will replace the present 8-MV tandem injector. Another four-rod RFQ has successfully operated at 18–40 MHz at RIKEN; it will be used to inject from a high-power ion source into RILAC. The efficiency of an RFQ in turning electrical power into particle energy is greater at high frequencies. RFQs could operate at harmonics of the cyclotron dee frequency, but the ion beam itself must be bunched to the lower, cyclotron, frequency to capture most of the ions leaving the ion source.

14.3.3
Altering the Beam Microstructure and Macrostructure

The typical cyclotron operates in continuous wave (CW) mode, producing a train of beam bunches, each a few nanoseconds long at the frequency of the accelerating field. These frequencies range from ~1 MHz for heavier ions to ~100 MHz for protons. There has been no macrostructure, that is, modulation at

lower frequencies, unless it was imposed by chopping the beam with a pulsed deflector or by pulsing either the ion source or the rf voltage, and these methods reduce the total charge delivered. Recently, cavities operating at some harmonic h of the main rf have demonstrated modulation of the time structure without loss of beam.

Consider that such a cavity to be installed approaches the outer radius of a cyclotron and provides an additional energy gain per turn ΔT_h that can be phased to either augment or oppose the energy gain ΔT_1 from the main rf. The phase Φ_r of some particle at radius r is obtained from

$$\Delta T_1(r_0)\sin\Phi_0 = \Delta T_1(r_0)\sin\Phi r + [k\Delta T_h(r)/h]\sin(h\Phi_r) \tag{1}$$

where Φ_0 is the starting phase at radius r_0. The parameter $k = 1$ when the additional cavity is phased to assist the main cavity in accelerating the beam. In this case, the width of the phase band decreases during acceleration from r_0 to r and phase compression is said to occur. The phase width is expanded when the additional cavity opposes acceleration – k is set equal to -1 in Eq. (1). In the latter case, the phase band can be split into two when $\Delta T_h > \Delta T_1$. The results of an experiment to confirm this are shown in Figure 14.4(a). The beam extracted from TRIUMF was a single bunch 3 ns wide at half maximum. This split into two bunches 8.5 ns apart when an additional cavity was turned on and its phase was adjusted to oppose acceleration. Figure 14.4(b) shows how further splitting is possible with the addition of extra cavities. This effect may possibly be exploited to match a cyclotron with a postaccelerator of higher frequency.

Large betatron oscillations can be excited by a kick from a pulsed deflector or by a field oscillating at the betatron frequency. If an extraction system – stripping foil or dc deflector – is placed at the point of maximum excursion, the beam extracted will have the time structure of the driving term. For example, calculations have shown that a stripping foil placed at a radius where Q_z is 0.25 and positioned above a deflector pulsed to impart a vertical kick every fourth turn to drive this resonance can provide a beam with three unpopulated rf buckets followed by a bucket four times as bright as normal.

14.3.4
Limitations to Beam Intensity from Cyclotrons

The most important advantage of cyclotrons for many ion-beam applications is the high beam current that they can deliver. It is useful to consider the factors that may limit beam intensity.

14.3.4.1 Space-Charge Limits

Coulomb forces between the constituent ions of the beam being accelerated oppose the focusing forces provided by the magnetic and electric fields. The most common limitation to beam current arises at low energy when this transverse space-charge force increases the height of the beam to the limit of the acceptance. This may occur in an axial injection system, in an inflector, or over the first few turns in

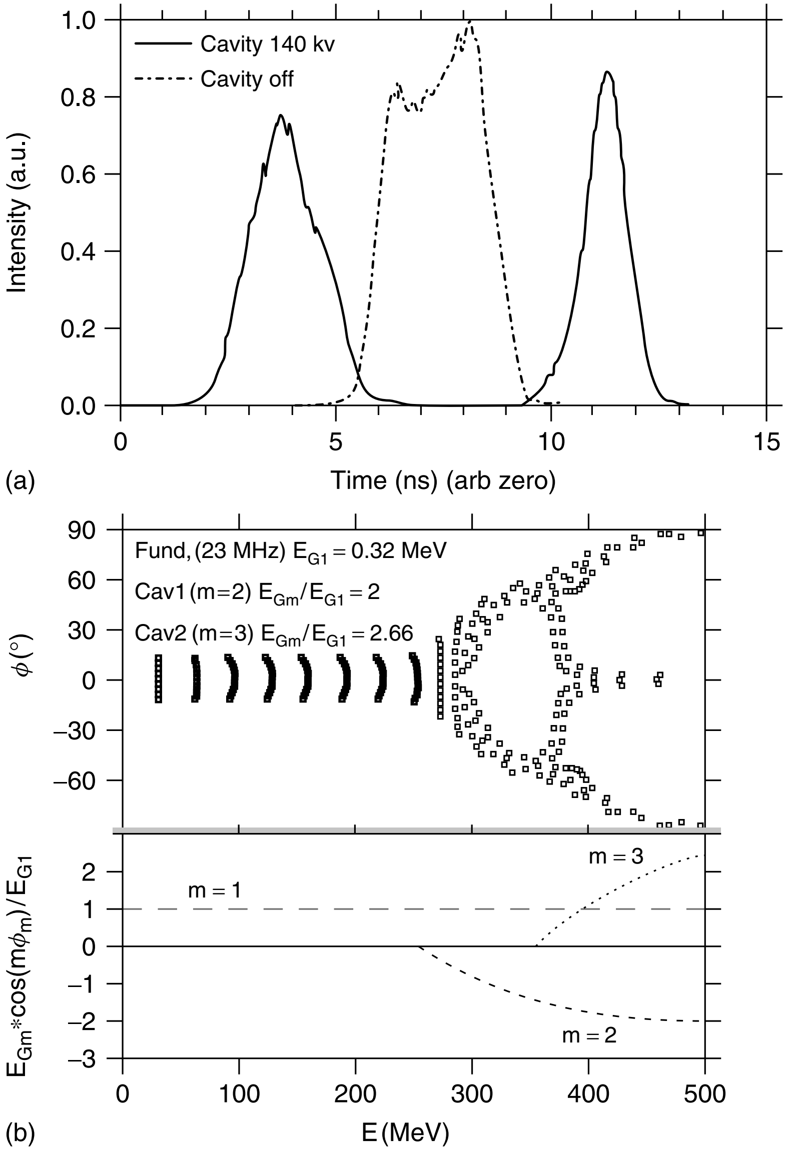

Fig. 14.4 (a) An experimental confirmation of beam splitting using one 300 keV/turn, $h = 4$ cavity at TRIUMF. One nanosecond is equivalent to 8.3° of phase for the main 23 MHz rf. (b) A computer simulation illustrating the splitting of a single phase band into three by means of two cavities operating at the second and third harmonics of the main accelerating rf.

the cyclotron where the limiting proton current, in amperes, is given by

$$I_{\max} = \beta \mathrm{B_f} \left(\frac{Q_z b \omega_{\mathrm{ion}}}{c} \right)^2 [7.8 \times 10^6] \qquad (2)$$

In Eq. (2), B_f is the bunching factor, defined as the ratio of average to local current, and b is the half-height of the accepting aperture. The other terms are defined in Chapter 13. A 1-MeV test-bed cyclotron with a solid pole, an intense external cusp H^- source, a spiral inflector, and an injection energy of only 25 keV has produced 2.5 mA of H^- ions at TRIUMF.

The ring cyclotron at PSI, which holds the record for beam power, has delivered 1.5 mA, or 0.9 MW, of 590-MeV protons. Beam is injected into the ring at 72 MeV, and low-energy space-charge problems are handled by the specially designed injector cyclotron. Within the ring itself, 10^{-4} of a 1 mA current is lost, and this loss scales as $1/N^3$, where N is the number of turns from injection to extraction. This is consistent with the limiting factor being longitudinal space charge, which tends to accelerate the front of the beam bunch and decelerate the rear. The bunch twists in the horizontal plane, increasing the overlap of turns and reducing the extraction efficiency. An extra rf cavity, oscillating at a harmonic of the main accelerating cavities, may ameliorate this situation by providing accelerating forces opposing those from space charge.

Cyclotrons normally operate in a steady state, and dynamic feedback between a beam signal and a subsystem is unnecessary. The rf cavities in the PSI ring cyclotron are illustrated in Figure 13.5. Four 50-MHz cavities accelerate the beam, and one 150-MHz cavity opposes their action to flatten the 50-MHz waveform over the length of a bunch. This flattening results in all protons having about the same energy in any given turn and thus increases the separation between turns and extraction efficiency. The 0.9 MW absorbed by the 1.5-mA beam is comparable to the power dissipated in the walls of the 50-MHz cavities. The 150-MHz cavity decelerates the beam and thus absorbs power from it, and at 1.5 mA, this absorbed power is also comparable with the cavity losses but has the opposite phase. The net phasor (voltage and phase) of the power supplied to this cavity depends strongly, therefore, on the beam current being delivered at that instant. PSI had to develop a fast feed-forward control system for the 150-MHz power supply in order to operate stably at these higher currents. The system uses the signal from a beam-current sensor to adjust the drive signal to the amplifier. In addition, an external load was added to the cavity to absorb both forward and reflected power at the cost of increasing the total power required (Sigg *et al.*, 1996).

14.3.4.2 Lifetime of Foils Used for Charge Exchange

Foils are used to extract a beam from a cyclotron by stripping (Cyclotrons, Section 14.3.5), or to increase the charge state of an ion to make more effective use of an accelerating voltage. The useful life of a foil is affected by the energy dissipated within it. Power dissipated by the passage of beam ions and stripped electrons can raise the temperature to a point where evaporation is important. Also the structure of the foil material may be altered at high temperatures, resulting in dimensional changes and curling or tearing of the foil; for example, pyrolytic graphite may be transformed into polycrystalline carbon. The carbon foils and monofilaments used to extract proton beams by stripping circulating H^- ions take 13 mAh mm^{-2}, or

$(2\text{ to }7) \times 10^{19}$ protons mm^{-2}, before curling. Lattice changes can also occur at normal temperatures; in fact this is the basis of some applications in the modification of materials. Heavy ions are most effective in displacing foil atoms because of their mass and short range. It was found at GANIL that carbon foils 150–400 μg cm^{-2} thick take only 3.6×10^{15} mm^{-2} of 13.6 MeV amu^{-1} argon ions before foil thickening renders the emittance of the outgoing beam unacceptable. For very thin foils Livingston, Berry and Thomas (1978) obtained

$$_{T}(p\mu\text{A- min -min}^{-2}) = \text{A} \times \text{T}^{1.13}(\text{MeV amu}^{-1}) \quad (3)$$

where the beam intensity is expressed in particle microamps (pμA) and the empirical constant A is 20 for argon. The rupture lifetime–intensity product τ may be extended >10-fold by more sophisticated manufacturing methods or by mounting the foils in an oscillating frame. Pure metal foils should be more resistant to lattice deformations than carbon; however, they must be thin to reduce scattering and to be able to handle the thermal power from the beam. The ISIS synchrotron uses 200 μg cm^{-2} Al_2O_3 foils successfully.

INTRODUCTION

Since the beginning of the last decade of this century the technical and economic importance of electronic displays has dramatically increased. It is predicted that the ever-growing application of displays will continue over many years to come. We are now only at the threshold of the "information age," which inevitably will stimulate new applications and new technical developments in the field of visual man-machine interface. In recent years we have already witnessed the appearance of flat-panel displays as daily commodity items. The market penetration of display-based products and systems occurs in an environment where digitized hardware and networks, advances in display technologies, and user-friendly software are rapidly developing. The information age provides new modalities like multimedia, high-definition television, and virtual reality on an internetworked global scale. Advanced storage and data-compression technologies allow for the provision of huge image data bases at one's fingertip. All these developments pave the way for an increased demand for user-friendly light and flat displays.

The intense market penetration of flat-panel displays is nearly completely to be credited to the products of liquid-crystal display (LCD) technology. In 1995/96 the production volume of high-information LCDs was two orders of magnitude larger than the sum of all other high-information content flat-panel technologies.

This Addendum will cover some of the new developments in the mainstream LCD technology; in the active light-emitting display technologies like field emission, plasma, electroluminescence, visible-light–emitting diodes; and in projection display technologies.

1. LIQUID-CRYSTAL DISPLAYS

1.1 Tailored Nematic Liquid-Crystal Materials

Liquid crystals appear in several "mesophases," which exist between the isotropic liquid phase and the highly ordered crystalline structure. Technically, the most important mesophases are the "nematic" (string-like) and the "smectic" (soapy) mesophases. Nematic liquid-crystal molecules consist of a flexible component such as an alkyl group and rigid components such as a biphenyl group and a cyano group. The cyano group serves to pro-

duce positive dielectric anisotropy (the difference between the dielectric constant in the direction of the long axis of the liquid crystal molecule and the dielectric constant at a right angle to the long axis). Molecular design efforts in recent years have involved replacing or modifying the three parts of a liquid crystal in order to synthesize new liquid crystals. This is illustrated in Fig. 1, which shows the main results of chemical modifications on the device performance (Yamazaki *et al.*, 1996). Properties that cannot be produced by molecular design are achieved by mixing various liquid crystal materials, as is being done to increase the practical temperature range.

When the liquid-crystal molecules are oriented by a surface alignment layer or by an electric field, the bulk sample has all the optical properties of an anisotropic crystal. LCDs operate by electronically modulating this anisotropy between two distinct optical states. The anisotropy is made visible with the aid of crossed polarizers.

1.2 Novel Addressing Schemes for Direct-Addressed Supertwist LCDs

In LCD matrix displays the driving circuitry sequentially selects the address lines, while the data information is sent simultaneously to all pixels in the selected line. Liquid crystals have relatively slow turn-on times; they respond to the time-average voltage (rms) instead of the instantaneous voltage. A selected pixel, which spends most of its time with its driving voltage below threshold voltage, has only a slightly higher rms voltage than a nonselect pixel. All contrast needs to be produced with only this small difference in voltage. This is why a highly nonlinear response is required as is provided by supertwist (STN) LCDs.

A drawback of STN is the inherent comparatively long response time (300 to 100 ms) and the chromaticity of the cell. To get rid of the chromaticity, double supertwisted nematic cells (D-STN) have been developed. Here a second LC panel containing a helix of the opposite orientation is placed in front of the first device. This technique later gave way to film-compensated STN (F-STN) in which the undesired coloration was compensated for by a phase-difference film.

The inherent response time of the display must be many times longer than the refresh time to satisfy the rms response condition. This generally rules out displays with response times short enough to show moving images at video rates. Indeed, if the display uses a "slow" LC mixture, the difference between OFF and ON states never gets large enough to generate good contrast. If the display uses a "fast" responding LC, then the contrast of an individual row begins to fade before the next refresh cycle begins, again deteriorating contrast. This phenomenon is called frame response—instead of responding to the average voltage applied over several frames, the LCD reacts to the relatively high-voltage row pulse within a frame.

The problem can be avoided by a completely different approach (Scheffer and Clifton, 1992: "Active Addressing^{TM}"; Ihara *et al.*, 1992; "Multiple Line Selection"). Instead of sending the high-voltage pulses sequentially down the rows, a set of predetermined signals are applied to multiple rows simultaneously and a unique calculated analog voltage is applied to the columns, depending on the state of the pixels in that column. The key is to determine which rows need which signal and to calculate the proper column voltage within the time frame available. One still has to provide an LCD cell that is capable of switching at video rates, i.e., decrease the cell thickness and use fast material.

The ultimate success of these novel addressing schemes will depend on the added cost of making these enhancements and the competition with active-matrix LCDs in terms of cost and performance.

1.3 Reflective LCDs for Low-Power Systems

Reflective color LCD without back light would be the enabling technology for multifunctional portable information terminals by which one could receive and send any information any time at any place. Such displays do not need heavy batteries and represent the most promising approach to "electronic paper" today.

A wide variety of reflective LC devices have been developed so far. A comprehensive description of the basic LC modes and design concepts has been given by Uchida (1996).

1.4 Chiral Nematic and Chiral Smectic Liquid Crystals

Both nematic and smectic liquid crystals forming a helical (chiral) structure are optically active. Optically active (chiral) nematic liquid crystals are also called cholesteric liquid crystals. They have the property of selectively reflecting or passing the light of a specific wavelengh if the pitch of their helical structure is equal to the wavelengh λ. This is the condition for constructive interference of light waves occurring if identical regions in the sample are separated by a distance of $\lambda/2$. Cholesteric liquid crystals can form one of three major textures depending on boundary conditions and applied fields: planar, focal conic, or homeotropic (Fig. 2). With increasing field strength the planar structure first transforms into a focal conic structure, then into a homeotropic aligned nematic state—which is highly transparent. The planar texture is highly reflective at a preselected wavelength and band-

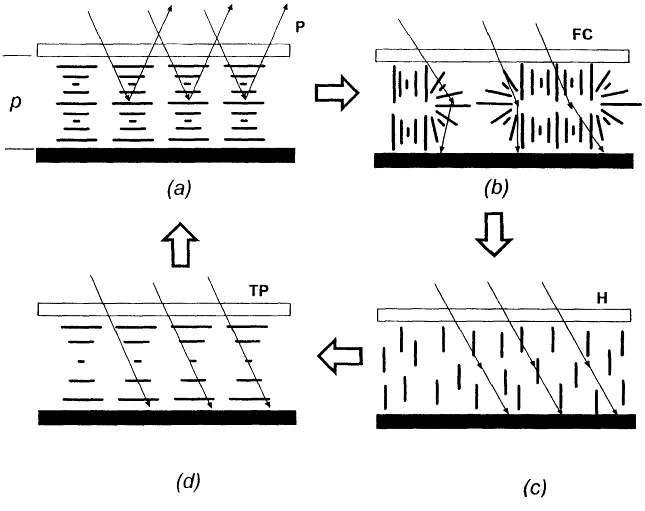

Fig. 2. Schematic textures in cholesteric liquid-crystal material: (a) light-reflecting planar texture; (b) nearly transparent focal-conic texture; (c) transparent homeotropic texture; (d) transient planar texture.

width. With the introduction of a polymer network or with suitable surface treatment of the cell substrates, a domain structure is introduced. This broadens the viewing angle, stabilizes the focal conic texture to create bistable switching, and introduces a gray-scale regime. The ability of the display to maintain pixels in both the ON and OFF states once they are written (without refresh) allows for unlimited resolution on a low-cost passive matrix without sacrificing contrast. Since a recent publication on a full-page size prototype (Pfeiffer *et al.*, 1995), renewed interest in this material is growing.

In the first engineering samples a total reflection around 40% was observed, substantially more than an ordinary reflective twisted nematic LCD. The achievable contrast is determined by transparency of the focal conic structure, which can exhibit a weak scattering. Different driving schemes are still under development. Real-time television has already been viewed on a cholesteric display cell at Kent State University (Doane and Stefanov, 1996). The technology has unique features like high resolution, low power due to bistability, and low cost, and seems to be very attractive for portable and handheld devices. The absence of polarization makes it possible to use low-cost plastic substrates—their inherent birefringence does not interfere with device performance. Principally polymer-stabilized cholesteric-texture devices could be one of the premier enabling technologies for electronic books, newspapers, or document viewers.

Optically active (chiral) smectic liquid crystals have a permanent electric dipole moment in the absence of an electric field, and for this reason they are called also ferroelectric liquid crystals (FLCs). The intrinsic polarization of these molecules, which is perpendicular to their long molecular axis (director), has the consequence that when subjected to an external field the molecules respond to the direction as well as the magnitude of the field. The helical structure would average out the direction of the spontaneous dipole, thus suppressing the ferroelectric behavior. Rubbed polymer surface alignment layers, similar to those in supertwist LCDs, remove the helical structure. The spacing between the two glass substrates should be about 2 μm. This spacing is also required for the ferroelectric liquid crystal cell to act as a half-wave plate. The operation of a FLC display depends on the switching of the FLC's dipole, whose orientation depends on the polarity of the addressing pulse (Fig. 3).

The FLC molecule cannot simply rotate

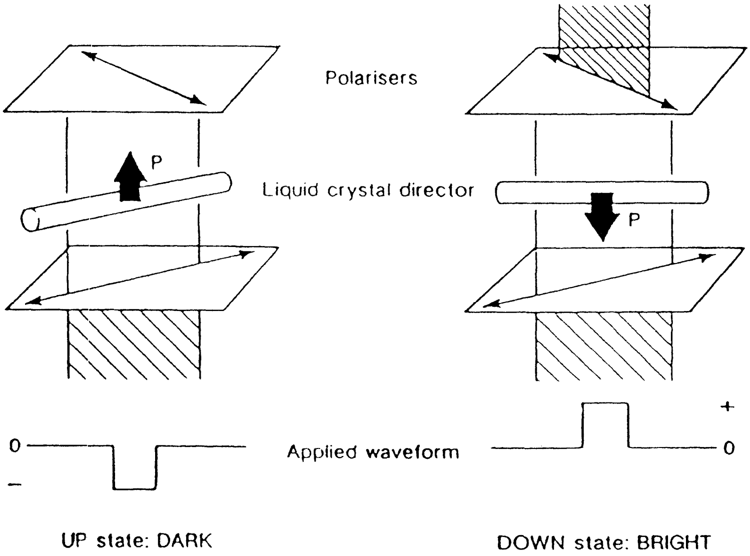

Fig. 3. An FLC display operates by changing the orientation of the LC molecule in the plane of the display.

about its own axis; instead it is constrained to rotate about an imaginary cone (Fig. 4). If the cone half-angle θ, which is equal to the tilt angle of the molecules in the smectic layer, is approximately equal to 22.5°, then the change in the orientation of the FLC molecules, 2θ, will be 45°. This is the angular change that produces the optimum values of transmission and contrast ratio (Mosley, 1997).

The two main attributes of FLC displays are very fast switching—typically 100 μs per row—and bistability. This property can be made use of to produce a nonvolatile display where the image is maintained at zero volts. The molecules switch in the plane of the display rather than perpendicular to it (as in supertwist and active-matrix LCDs). This leads to a very good viewing angle. The main obstacles in the commercialization of ferroelectric LCDs have been production issues (very small distance between substrate plates), the absence of gray scale, and susceptibility to mechanical shock, although it is said that there are solutions to these problems. In addition to ferroelectric LCDs there are also antiferroelectric LCDs. Yamada *et al.* (1995) have developed a display with gray scale and have demonstrated high-quality video images on a $125 \times 80\text{-mm}^2$ display area.

1.5 Active-Matrix-Addressed Liquid-Crystal Displays (AMLCDs)

Active-matrix addressing has been the most broadly pursued technology to enhance liquid-crystal display performance. In 1996 the world market for AMLCDs was estimated to be about US\$$6.1 \times 10^9$; a global turn-over in the order of US\$$10 \times 10^9$ is expected around the year 2000.

Active-matrix addressing leaves the fundamental twisted nematic operation unchanged and uses pixel-external nonlinear devices to enhance the contrast of large multiplexed displays. The devices do not respond to the rms time-average voltages but rather to the instantaneous peak voltage. Two- or three-terminal thin-film devices act as switches, electrically isolating a pixel until its input voltage exceeds a certain specified threshold. Pixels in active-matrix devices are driven at duty cycles close to 100%. The voltage at the pixel remains practically constant during each frame, as if the pixel were directly driven. The pixel acts as a capacitor storing the charge and maintaining the voltage during the frame time. Thin-film transistors (TFTs) formed by sophisticated deposition and patterning technologies are the most frequently used switches in AMLCDs commercially available. The semiconductor material used for the TFT in most cases is amorphous silicon because it can be fabricated at relatively low temperatures and generates high image quality. The use of polysilicon material would allow the integration of driver circuits on the same glass plate because of the much higher mobility achievable. On account of high process temperatures polysilicon is not compatible with normal glass substrates. Laser or furnace annealing are key processes for the advancement of polysilicon AMLCD technology. For details of the fabrication the reader is referred to Morozumi (1996).

AMLCD manufacturers now are moving into the third level of development with significant improvement issues. The coming wave of AMLCDs is intended to at least partially replace CRT monitors. This means that competitive size, cost, and performance of the flat displays will be of paramount importance. In 1995 the AMLCD mass product was the VGA 10.4-in. (26.4-cm) panel. Now the trend has shifted to 11.3-in. (28.7-cm) and 12.1-in. (30.7-

cm) SVGA panels. The size enlargement will continue to 13.3 in. (33.8-cm) in XGA resolution with future options in the 15- to 17-in. (38.1- to 43.2-cm) range. Manufacturers are shifting their 390 × 470-mm^2 or 400 × 500-mm^2 substrate sizes to 550 × 650 mm^2 and will ultimately be targeting even 1 m diagonal size. They will simplify their array processes by lowering the number of photo masks and eliminate rubbing by photo alignment technologies. They will have to develop means to lower the resistance of bus lines. At the same time they are striving to widen the viewing angle and reduce power consumption of the panels. Figure 5 shows a cross section of a color AMLCD module and indicates how the driving circuitry is connected to the glass substrate carrying the TFTs. Mostly anisotropic conducting films are used to connect the ITO pads on the glass to the driver LSIs. Another connection method would be chip-on-glass.

Several technologies have been proposed to improve the originally rather narrow and nonuniform viewing characteristic of single-domain twisted nematic cells. Two of the major technologies are the formation of multi-domain cells with reversed LC orientations in each domain (by multiple rubbing and photolithographic processes) as suggested, e.g., by Kaneko *et al.* (1993) and the in-plane switching as first devised by Kiefer *et al.* (1992) and implemented by Kondo *et al.* (1996).

Standard AMLCD have five electrodes: three for gate, source, and drain of the transistor, one for the pixel electrode, and one common electrode. In most cases the common electrode is formed on the counter-substrate. As shown in Fig. 6, in-plane switching uses an interdigital electrode structure. The five electrodes are arranged in two layers on the TFT substrate side. The lower layer carries the gate and common electrodes, the upper one the source and drain electrodes, which are co-used as pixel electrodes. This approach avoids the indium-tin-oxide transparent electrode on the counter-substrate. The electric field is no longer vertically but horizontally oriented as indicated by the arrows in Fig. 6. Under the influence of this field the optical axis of the nematic LC molecules deviates from the polarization axis and the transmittance of incident light through crossed polarizers is gradually increased. Horizontally and vertically 70° viewing angle in both directions has been achieved at a contrast ration of 10.

The overall transmissivity of AMLCDs is determined by the transmissivities of the glass, 95%, the polarizers, 35%, the color filters, 25%, and the cell aperture (that portion of the cell which is transparent to light), which depending on design can vary between 40% and 65%. As a result the overall transmissivity of the cell is not more than 3.3% to 5.0%! One of the major research issues for AMLCDs is to improve transmissivity to reduce power consumption. The two other areas to work on for further

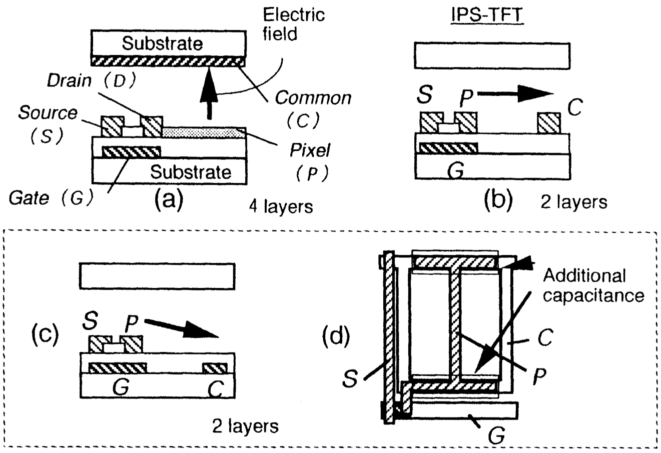

Fig. 6. (a) Cross section of conventional AMLCD and (b) in-plane-switching. (IPS-AMLCD). (c) In the IPS version the common electrode is located in the gate electrode layer. (d) The planar arrangement of (c) (after Kondo *et al.*, 1996).

power reduction are improvement of the efficiency of backlights and reduction of the power consumption of the drive-circuit unit. As a result of a comprehensive optimization the power consumption of a 10.4-in. (26.4-cm) SVGA AMLCD with a luminance of 70 cd/m^2 could be reduced from 3.5 W to 1.5 W (57% reduction) or with the same power consumption the luminance could be raised to 120 cd/m^2 (+72%) (Ohshita, 1996).

1.6 Plasma-Addressed Liquid-Crystal Displays

Despite their immense success in the portable display area and the anticipated large market share they might conquer in the monitor market in the near future, it is not predicted that AMLCDs will be available as meter-sized panels for consumer HDTV in the next ten years. The scaling difficulties of photolithography and metallization to sizes larger than 25 in. (63.5 cm) can elegantly be bypassed by a new approach called plasma-addressed liquid crystal (PALC) (Buzak, 1990). PALC uses the electrical switching properties of an ionized gas to address the liquid-crystal pixels actively. In the integrated LCD/plasma structure of the PALC, each scan line is defined by a plasma channel. The cathodes in the channels are sequentially scanned by applying a plasma discharge voltage that produces a full plasma within several microseconds. The analog video signals are fed to each column electrode. Except for the one row where the gas is ionized, the analog voltage has no effect on the light transmissivity of the liquid crystal since there is no electrical connection or conductor on the bottom side of the liquid crystal. Along the line above the ionized channel, however, the pixel capacitance can charge to the value determined by the data voltage. In effect, the plasma completes the electrical circuit between the data electrodes and the grounded channel electrode. Kakizaki *et al.* (1996) have presented a 25-in. (63.5-cm) PALC display for wall-hanging TV with 1.8 lm/W light efficiency, 250 cd/m^2, and high contrast even in bright ambient.

2. ACTIVE DISPLAYS

Active, self-emitting displays do not need any backlight. Every pixel emits light (and uses power) only as long as this is required for the image buildup. In the backlit LCDs every pixel including the OFF pixels receives full backlight power as long as the display is operating. In terms of energy management active displays have a conceptual advantage. On the other hand the separation of the functionalities "pixel addressing" and "light emission" allows a separate optimization of both. In the case of AMLCD this freedom in design has led to an overall energy consumption which is lower than in any active light-emitting device.

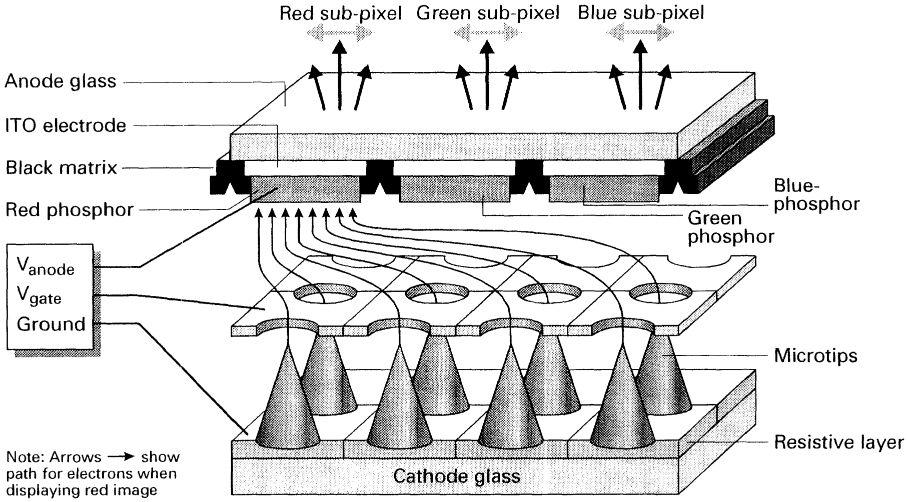

Fig. 7. Basic structure of field-emission displays (courtesy of PixTech).

2.1 Field-Emission Displays (FEDs)

The operating principle of these newly emerged vacuum electron devices is comparable to vacuum-fluorescent displays with the important difference that the electrons are not emitted by thermal activation from hot filaments but rather by field emission from a cold cathode. Electrons escaping from the cathode are accelerated towards a phosphor screen, where their energy is partly transformed into light (Fig. 7). In FEDs electrons are generated by a voltage difference between the cathode and closely positioned gates according to the Fowler–Nordheim tunneling equation for field emission.

Field enhancement induced by tips is the most widely investigated method to obtain useful currents at moderate macroscopic fields. One way of fabricating microtips is to make use of the wet etching properties of *n*-silicon (Jiang and White, 1993). This approach limits the display size to the available diameters of Si wafers. Meyer (1990) and his group have developed a fabrication process for molybdenum microtip cathodes on glass. The process also provides a gate electrode with a 1.4-μm self-aligned hole around each cathode tip. This original design was refined through the addition of a ballast resistive layer to average out random fluctuations of current yield between tips. The negative electron affinity on diamond-like carbon surfaces has fueled research in diamond emitters as a low-cost manufacturing alternative (Kumar *et al.*, 1994). The lwo-cost cathode architecture allows only the design of diode-type FEDs with the inherent disadvantage that gray scale is difficult and expensive to obtain (Courreges, 1996).

A big challenge in FED construction is the anode technology. The anode acceleration voltage determines the penetration depth of electrons into the phosphor grains. At low acceleration voltages, below 1000 V, the RGB phosphors are deposited on a conductive transparent electrode on the anode glass. If the phosphors are deposited on electrically isolated comb-like ITO structures, switched-anode FEDs become possible. Here the cathode is time multiplexed with a sequential addressing of color anodes as shown in Fig. 7. As a result of small electron penetration depth in the low-voltage approach, the grain surface largely determines the efficiency and the ultimate brightness. At higher acceleration voltages, above 5 kV, the phosphors can be covered by a thin layer of aluminum to provide surface conduction and avoid charging up. Here efficiency and brightness come close to those of CRTs. Low-voltage architecture avoids the need for focusing and allows for a low-cost spacer technology in the 200-μm cell gap. For high voltage the cell gap has to be increased at least ten times, which leads to

Fig. 8. Two designs for color ac plasma displays.

complex solutions for the focusing and spacer technologies to suppress arcing and sputtering effects. The future will show whether the attractive properties of FEDs will prevail in terms of cost/performance ratio.

2.2 Plasma Displays (PDPs)

Plasma-display technology has gained a strong momentum in recent years. Demonstrations of exceptional large-area image quality have generated new interest in this 25-year-old technology. Plasma is now regarded as the leading direct-view flat-panel technology for large-area (meter-sized) displays. After the successful prototype demonstrations of 42-in. (107-cm) diagonal plasma displays, the major challenge now is to achieve high-volume manufacturing at affordable cost.

Like LCD panels, PDPs consist of two glass plates with helium or neon gas with an addition of 3 to 10% of xenon gas sealed between them. Electrodes are formed at the inner surface of the glass plates. To avoid catastrophic arc the current in the gas discharge must be limited: dc plasma displays use a resistor, and have the electrodes in intimate contact with the gas discharge; ac plasma displays limit the current with an internal glass dielectric covering the electrodes, which are capacitively coupled to the gas discharge.

In color PDPs the Xe component of the gas mixture emits ultraviolet light in the 147-nm range. In a line-at-a-time scanned-matrix display the overall brightness decreases with increasing number of scanned lines. It is very helpful in this respect that for both ac and dc plasma displays an inherent memory function is available. RGB light emission is achieved via the photoluminescence of phosphors excited by the UV light.

Two ac plasma-display electrode configurations are shown in Fig. 8.

The single-substrate structure separates the discharge cathode areas from the phosphor by applying the sustain voltage only the lower electrodes while the phosphor is on top. This approach avoids direct bombardment of the phosphor by energetic ions. The basic structure of single-substrate ac plasma displays is shown in Fig. 9.

The front glass carries the two parallel transparent sustain electrodes for each pixel. On the rear glass substrate the RGB phosphors are deposited on top of the address electrodes, separated by barrier ribs to avoid color cross-talk. The two glass plates are aligned orthogonally, forming pixels automatically at the intersection of the orthogonal electrodes. In PDP production the fabrication of the barrier ribs with their high aspect ratio (50 μm wide and 130 μm high) is a formidable

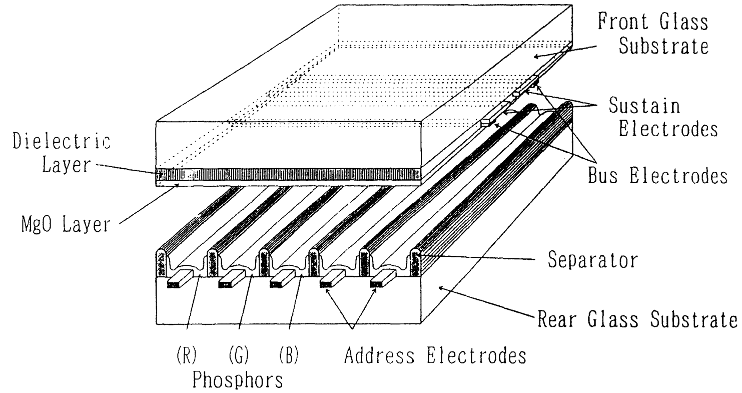

Fig. 9. Structural details of Fujitsu's ac plasma television screen.

problem. For low and medium resolution, multiple-screen printing can be used. For high-resolution displays this process is not suitable. For high-density barrier-rib formation, sand blasting and photosensitive molding of glass paste are being investigated.

In current generations of PDPs lamp phosphors like $(Y,Gd)BO_3:Eu$ are used for red, $BaMgAl_{14}O_{23}:Eu^{2+}$ for blue, and $Zn_2SiO_4:Mn$ for green emission. Phosphor aging is an important issue but seems to be solved. Probably the greatest challenge for plasma-display engineers is to increase the luminous efficiency of the devices. 0.7 lm/W is the highest efficiency reported so far for a commercial full-color plasma display (Shinoda, 1993). To increase this value improvements in the discharge efficiency, better optical coupling, and higher phosphor efficiencies have to be achieved.

To obtain gray scale in the memory mode of ac and dc plasma displays, the time that the pixel is ON in a given frame rate is modulated. This means that the pixels must be addressed multiple times per frame. In a binary chop technique, e.g., a 256-intensity gray scale would require 8 addresses per pixel per frame (Weber, 1996).

2.3 Electroluminescent Displays (ELDs)

2.3.1 Electroluminescence in Inorganic Materials. The performance of inorganic color thin-film electroluminescent (TFEL) displays has made significant progress in recent years due to the improvements of color phosphor materials with blue and broadband emissions. The reader is referred to the comprehensive article ELECTROLUMINESCENCE, together with its Addendum.

The classical EL phosphor is the yellow-emitting $ZnS:Mn$. This large–band-gap semiconductor is sandwiched between two insulating thin films and operated with ac voltage. The power dissipated in generating light is $8\,mW/cm^2$. Accordingly the power required to generate light from a 10-in. (25.4-cm) VGA display is just over 1 W; the luminous efficiency is 6 lm/W.

Two parallel roads have been taken to achieve color EL:

1. the development of an efficient white (broadband) phosphor that can be filtered and
2. the development of efficient red, green, and blue primary-color EL phosphors.

Tuenge and Karne (1991) have shown that an efficient red emission (1 lm/W) can be achieved with the combination of the standard yellow $ZnS:Mn$ phosphor and a red filter. The green $ZnS:Tb$ phosphor also has an efficiency near 1 lm/W (Härkönen *et al.*, 1990). In the blue part of the spectrum for some time the efficient $SrS:Ce$ phosphor was available. Actually this phosphor has a blue-green chromaticity and requires filtering to achieve a true blue color. Barrow *et al.* (1993) achieved an important breakthrough by showing that a group of ternary sulfides (thiogallates:

MGa_2S_4 where M stands for Ca, Sr, or Ba) activated with Ce were efficient blue-emitting phosphors.

White EL phosphors were first based on the broad emission of the system SrS : Ce,Eu, but the achieved brightness did not satisfy the needs of high-information displays. White emission from stacked layers of ZnS : Mn and SrS : Ce phosphors has achieved the luminance level required for filtered color ELDs. A white luminance of $340\,cd/m^2$, and red, green, and blue filtered luminance values of 39, 90, and $18\,cd/m^2$ at 60 Hz have been obtained by Velthaus *et al.* (1994) using a multilayer structure with 9 layers. The peak luminance could be further increased to $470\,cd/cm^2$ by dual layers grown by atomic-layer epitaxy (Soininen *et al.* 1994).

2.3.2 Electroluminescence in Organic Materials. Electroluminescence can also be obtained from numerous organic materials. Following the pioneering work of Tang and Van Slyke (1987) and Burroughes *et al.* (1990), research efforts have been directed at developing efficient organic EL devices based on thin films, driven typically below 10 V. Substantial improvements in efficiency, color, and stability of the devices have been achieved.

Organic EL devices generally consist of a hole-transport layer (HTL) and an electron-transport layer (ETL) sandwiched between current-injecting electrodes. Potential barriers at the interface of the two layers localize electrons and holes and thus enhance the probability of their recombination in this area. Also, the channel for radiative recombinations can be further optimized by introducing fluorescent centers near this interface. The two-layer structure is thus extended to include a thin emitting layer (EML) between HTL and ETL. The three-layer structure is particularly useful in tuning the EL colors (Tang, 1996).

The current in the organic layers in the EL device is principally space-charge or injection limited. Space-charge limitation is avoided by using organic films only a few hundred nanometers thick. As ETL organic materials, often a complex of 8-hydroxyquinoline with a *tris* ligand configuration around the central Al ion (called Alq) is used, while the EML contains a small amount of fluorescent molecules and the HTL is made of an aromatic amine material. Another successful approach is the use of light-emitting polymer material for the fabrication of flexible full-color displays. Low-barrier contacts are designed by matching the organic layers with electrode materials of proper work functions like Mg : Ag or Al : Li as cathode material and ITO for the anode. Red, green, and blue light-emitting devices have been obtained with efficiencies above 1 lm/W. Depending on the luminance output, operational half-life on the order of several thousand hours is achievable from orgainc EL emitters.

2.4 Visible-Light–Emitting Diodes (LEDs)

Visible LEDs have been on the market since the 1960's. Only in the last few years, however, have high-performance LEDs been available in all colors, allowing the fabrication of full-color flat-panel displays viewable in direct sunlight. Before 1985, when LED performance was generally in the range of less than 2 lm/W, LEDs were mostly limited to indicator-type applications. Since 1985 the performance has increased to as high as 50 lm/W for the highest performance type of red-emitting AlInGaP LEDs, With the development of GaInN devices, the range of colors has expanded to include the violet, blue, and pure green such that high-performance LEDs are available throughout the color spectrum. With an efficiency that exceeds many types of conventional lighting sources, LEDs can now be used in a variety of new application areas such as vehicle lighting, traffic signals, road signs, and large-area displays for advertisement. Red-light–emitting high-performance devices in AlGaAs technology were first introduced to the market around 1983. In 1991 red, orange, yellow, and green light-emitting diodes based on AlInGaP came up (Kuo *et al.*, 1990; Sugawara *et al.*, 1991). In 1993 this was followed by the successful commercialization of a new materials system for the green and blue part of the visible spectrum: the InGaN system (Nakamura *et al.*, 1995). The luminous efficiency vs. emission wavelength for commercial LEDs is shown in Fig. 10.

The AlInGaP system shows the highest performance in the red and amber region; the efficiency degrades sharply towards the green region. Nevertheless green AlInGaP LEDs can

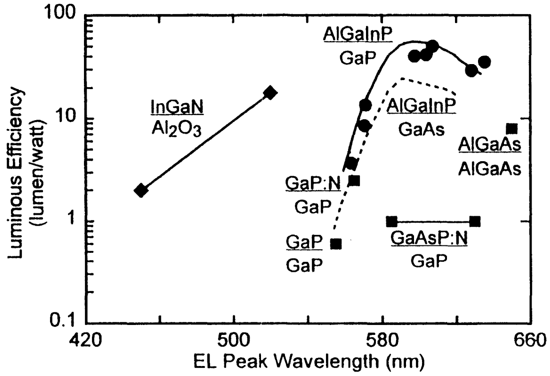

Fig. 10. Luminous efficiency of different materials systems vs. peak wavelength (after Craford, 1996).

be produced with an efficiency still doubling that of the conventional GaP : N green devices. The wavelength, however, being 560 nm or greater, is perceived as a yellowish green and therefore is not suitable for many full-color applications. The efficiency degradation towards the green is due to the fundamental transition in the band structure of the semiconductor alloy, which changes from "direct type" to "indirect type" with much less light-generation efficiency. The direct-to-indirect change is also the reason why AlGaAs LEDs work well in the infrared and red but not in the green part of the spectrum. The InGaN material system is a direct-type semiconductor all the way from the red to the ultraviolet. The best devices have been made in the blue and green regions. In the yellow there is a sharp falloff due to problems with materials growth and a bad match in atomic spacing between the different layers of the device structure.

3. PROJECTION DISPLAYS

In 1995 the total market for projection displays was in the order of US $ 4.6 billion. 58% of this market was covered by CRT-based products, and 42% by LCD-based products. The range of these products includes projectors for video home theater applications, projectors for overhead presentations, head-up displays for automotive systems, and many more.

At the heart of the projector is the light engine, which converts the electrical signal to an optical image (Stupp, 1996). The light engine can be either light emissive or light modulating. In the light-emissive group we find the CRT projectors and systems under development like field-emission or laser-based projection systems. Light-modulator systems employ either light-valve (LV) or light-amplifier (LA) systems to modulate the output light spatially.

The typical CRT projector uses three CRTs and three lenses—one for each of the primary colors. Consumer projectors are mostly CRT-based rear-projection systems with the light passing through a viewing screen to the viewer. The screen consists of a Fresnel lens and a double lenticular lens to minimize color separation in the image resulting from the angular separation of the sources.

LV or LA projector systems can be based on one or more (usually three) LVs. The systems based on multiple light valves often use dichroic mirrors and filters to separate the white light into color bands and to recombine the spatially modulated bands into a single converged image. Color information in single-LV systems can be obtained either by color-field sequence, by microfilters on the panel, or by angular color separation. The typical light source for LV systems is a high-intensity discharge lamp or occasionally a tungsten halogen lamp. The efficiency of light collection and utilization is determined by the size of the light arc, the area of the LV, and the usable angles of illumination. Since the peak white intensity is continuously generated, the maximum contrast achievable is determined by the attenuation capability of the LV. Active-matrix LCDs (frequently in the polysilicon version) are the most commonly used LVs in LCD-based projection systems. Polymer-dispersed LCDs are of specific interest, because they do not need polarizers with their inherent optical losses.

Another LV technology entering commercial application is based on micromechanics (Sampesell, 1993). The Digital Mirror Device^{TM} (DMD^{TM}) consists of an array of square mirrors ($17 \times 17\,\mu m^2$) torsionally suspended over a surface of monocrystalline silicon containing SRAM and other CMOS circuitry. The mirrors are tilted to $\pm 10\,^\circ$ under the influence of voltages from the underlying address circuitry. When the mirror is in the $+10^\circ$ position, the light from the lamp enters the projection lens and is transmitted to the screen. In the -10° position, the light misses the lens and is internally absorbed. Gray scale is achieved by time-multiplexing the position of the mirror. The switching speed is sufficient to achieve 8 bits per color in a 60-Hz frame time.

In LA devices the signal "writing" is done optically rather than electrically with an active matrix. The devices are multilayered. The input side consists of a photoconductor such as amorphous Si coupled to a reflective liquid-crystal cell that forms the output stage. A CRT or other light source is imaged onto the input photoconductor, generating an electrical image, which is transferred to the LC cell. An intense illumination onto this output stage is modulated by the cell, as with an LV. The input and output sides of the LA are separated by an efficient dielectric mirror that is part of the reflective LC cell and by a light-blocking layer to keep the output illumination from degrading the response of the input photoconductor.

Another emerging technology is AMLCDs fabricated on crystalline silicon wafers. These reflective-mode devices offer the potential of small pitch and high aperture ratio. In transmissive LVs, the aperture ratio is limited by the address lines and the TFTs. In reflective cells these can be fully hidden under the reflective back electrode. As with the DMD^{TM}, this produces small interpixel spacings with high aperture ratios.

1. EARTH STRUCTURE AND COMPOSITION

Significant progress has occurred in seismic tomography. The resolution in detecting velocity heterogeneity has been improved, and it is now well established, on the basis of both P-wave and S-wave tomography, that some subducted slabs penetrate down to the bottom of the lower mantle (North and South America), although others appear to be deflected near the 660-km discontinuity (e.g., in the western Pacific) (e.g., van der Hilst *et al.*, 1997). These latter slabs, however, also are likely to reach to the bottom of the lower mantle after a certain time, judging from the correlation of high-velocity anomalies at the bottom of the mantle and the history of subduction. Variation of the behavior of subducted slabs appears to correlate with the velocity of trench migration and the temperature of slabs: slab penetration deep into the lower mantle occurs where the velocity of trench migration is small and/or the temperature of the slabs is high (young and/or fast subducting slabs). Thus, the style of mantle convection appears to be neither a simple whole-mantle convection nor strictly layered convection at the present time and during the recent past.

Seismic tomography has also shown large-scale low-velocity anomalies at the bottom of the mantle. They are located beneath the south Pacific and Africa. The presence of partial melting is suggested (Williams and Garnero, 1996). These regions are the likely source for plumes that result in ocean island volcanoes. However, plumes with shallower sources (transition zone) are also inferred (e.g., in Europe).

The presence of anisotropic structures in the inner core has been established both by the analysis of body-wave travel-time anomalies and by the analysis of anomalous splitting of free oscillation peaks. The anisotropy is rather large ($\sim 3\%$) and has nearly axial symmetry, with the symmetry axis slightly ($\sim 10°$) tilted with respect to the current rotation axis (e.g., Song, 1997). The anisotropy is best explained by the preferred orientation of anisotropic iron crystals in the inner core, although neither the physical mechanisms of alignment nor the crystal structure of iron in the inner core is well understood. By analyzing old seismic records, two groups of seismologists have detected the migration of the pole of anisotropy, suggesting rotation of the inner core with respect to the mantle (Song and Richards, 1996; Su *et al.*, 1996). It is remarkable that this "super-rotation" of the inner core was predicted by theoretical modeling of the geodynamo as caused by magnetic coupling between the inner and outer cores (Glatzmaier and Roberts, 1995).

In contrast to the inner core, the bulk of the Earth's mantle is nearly isotropic except for the near-surface layer (lithosphere and asthenosphere), the D$''$ layer (the bottommost layer of the mantle), and possibly the layer near the 660-km discontinuity. Anisotropy in the mantle is likely caused by lattice-preferred orientation of elastically anisotropic minerals such as olivine or perovskite or by laminated structures. Boundary layers of convection are the likely place to cause seismic anisotropy be-

digital Encyclopedia of Applied Physics

cause of highly concentrated deformation at high stresses and the accumulation of chemically distinct materials that tend to form laminated structures. Thus the presence of strong anisotropy in the top and the bottom (D″) layers indicates that they are the boundary layers of convection, and also that the possible presence of an anisotropic layer around the 660-km discontinuity suggests the presence of a mid-mantle boundary layer, implying that convection is somewhat layered. It is surprising that the bulk of the lower mantle is nearly isotropic despite the fact that its constituent minerals are highly anisotropic. The most likely explanation is to assume that the deformation mechanism in the lower mantle is grain-size–sensitive diffusion creep. In this case, rheology is linear (rate of deformation increases linearly with stress) and the grain-size reduction due to phase transformations in downgoing slabs will cause significant rheological weakening.

New seismological observations on gross Earth structure include the evidence of the 520-km discontinuity and a discontinuity around ~1000 km in some areas (e.g., Kawakatsu and Niu, 1994). These discontinuities are rather subtle as compared to those at ~410 km and at ~660 km, which are more distinct and are global features. The 520-km and ~1000-km discontinuities may be regional as opposed to global. The 520-km discontinuity may be attributed to a phase transformation in Ca-rich silicate to $CaSiO_3$ perovskite, but the origin of a discontinuity around 1000 km is uncertain. No phase transformations in major minerals are known at conditions equivalent to this depth. A chemical layering caused by subduction of oceanic lithosphere is a possible mechanism.

The chemical composition of the Earth's mantle has continuously been a subject of extensive studies. Advances in high-pressure technology combined with high-energy x-ray sources from synchrotron radiation now allow us to measure directly the molar volume of minerals under conditions equivalent to the shallow lower mantle (to ~1000 km depth). Experimental techniques to measure seismic-wave velocities under deep-Earth conditions (to ~500 km deep so far) have also been developed. With these techniques, the density, compressibility, and thermal expansion of $MgSiO_3$ perovskite have been determined under shallow lower-mantle conditions (Funamori *et al.*, 1996). Also, seismic-wave velocities of the α (olivine) and β (modified spinel) phases of $(Mg,Fe)_2SiO_4$ have been measured near conditions equivalent to the 410-km depth. The results of these studies have been compared with seismological observations to place constraints on the chemical composition of the Earth's mantle. The main issue here is if the Earth's mantle is chemically layered or not. Despite much progress in high-pressure mineral physics, the issue is far from resolved. The major difficulty is the trade-offs among various parameters (e.g., temperature, iron/silicon content). For example, seismological data can be fitted to either a chemically homogeneous model or a chemically layered model with some iron and/or silicon enrichment in the lower mantle, when a significant temperature increase around the 660-km discontinuity is assumed. However, in view of the strong evidence of penetration of some downgoing slabs into the lower mantle, a strictly chemically layered mantle structure appears to be ruled out.

One important discovery in mineral physics is a dramatic effect of Al on the crystal structure of $(Mg,Fe)SiO_3$ perovskite. It was found, from high-pressure experiments using a multi-anvil apparatus, that a small amount of Al changes the valence state and the crystallographic site of Fe in perovskite (Wood and Rubie, 1996). Fe appears to occur mostly as ferric iron and occupies six-coordinated sites (similar to Si) when a small amount of Al is present. This behavior affects the partitioning of Fe between perovskite and magnesiowüstite and also is likely to change other physical properties including electrical conductivity and elastic properties. Discussions on the chemical composition of the lower mantle will have to take this point into account.

Another potentially important source of information to place constraints on the chemical composition of the deep interior of the Earth is the chemical composition of rocks that are carried from the deep interior of the Earth. During the last few years, several rocks have been discovered that are considered to have originated in the transition zone or the lower mantle of the Earth on the basis of their mineralogy. They include peridotites from South Africa containing unusually silica-rich garnets, a peridotite from the Swiss Alps containing olivine grains with exotic Ti-rich inclusions, and diamonds from Brazil that contain a pair of minerals (magnesiowüstite and pyroxene) that could have been in chemical equilibrium in the lower mantle. These rock specimens provide direct information as to the chemical composition of the deep interior of the Earth. However, the relevance of their compositions to the composition of average Earth's mantle is not always clear, because these samples may have been carried from some unusual regions.

The sharpness and the regional variation in depth of seismic discontinuities have been studied in detail. Many of the seismic discontinuities appear to be rather sharp (major changes in physical properties occur within a few kilometers interval in most cases). Regional variation in the depths of these discontinuities has also been detected. The most marked one is the variation in the depth of "660-km" discontinuity. The depth of the "660-km discontinuity" (boundary between upper and lower mantles) appears to vary on a regional scale (Shearer and Masters, 1992). It is significantly deeper than average in the regions where the temperature is considered to be lower than average as a result of the subduction of oceanic lithosphere. This is consistent with the results of mineral physics, which indicate that the phase transition from upper-mantle minerals to lower-mantle minerals occurs at higher pressures at lower temperatures. The depth of the 410-km discontinuity does not vary as much as that of the 660-km discontinuity. Because the temperature sensitivity of the depth of the phase transformation corresponding to the 410-km discontinuity is as large as that of the 660-km discontinuity (but with a different sign), this observation suggests that lateral variation in temperature around the 410-km discontinuity is not as large as that around the 660-km discontinuity.

2. MANTLE DYNAMICS

The study of mantle convection through computer simulation has made major progress during the last few years. The increasing capability of computation allows incorporation of more and more "realistic" physical properties in numerical modeling. The most important result in this area is the demonstration that the density contrast associated with the 660-km discontinuity has an important effect in modifying the convection pattern. The lateral density contrast near the 660-km boundary as inferred from the undulation of the 660-km discontinuity tends to prevent vertical mass transfer across this boundary. The results of numerical modeling during the early 1990s showed that this effect is large enough to change convection pattern to intermittently layered convection when the contrast in viscosity between descending currents and the surroundings is small (e.g., Tackley, 1995).

In contrast to the effects of density variation, the effects of viscosity structures on the style of convection are less well understood. The viscosity profile in the Earth's mantle is much less constrained than the density profile, but viscosity could change very dramatically both radially and laterally (e.g., Karato, 1997). Recent analysis of vertical crustal movement associated with the post-glacial rebound combined with the analysis of Earth's rotation and geoid observations yields a unified model characterized by a significantly higher viscosity in the deep lower mantle than in the upper mantle (Forte and Mitrovica, 1996). Such a viscosity profile provides a natural explanation for the fixed position of hotspot volcanoes, which may be caused by plumes originating in the deep portions of the lower mantle. Lateral viscosity variation, particularly the viscosity of subducting lithosphere, has been shown to significantly affect convection patterns. The significant role of the density contrast associated with the 660-km discontinuity in changing the convection pattern is important only when the descending current does not have much higher viscosity than the surrounding mantle. The observed significant deflection of subducted oceanic lithosphere in the western Pacific therefore suggests that subducted lithosphere there is rather weak. Likely causes of weakness include grain-size reduction associated with phase transformation(s) (Riedel and Karato, 1997).

Deformation in deep subducted oceanic lithosphere often occurs through seismic faulting. The origin of these deep earthquakes has been an enigma, because brittle fracture that is responsible for shallow earthquakes is impossible under high confining pressures. The role of phase transformations in causing instabilities in deformation has been demonstrated in laboratory studies, which provides a potential mechanism for deep earthquakes (Green, 1994). However, the new data obtained from the Bolivia and the Fiji deep earthquakes during 1994 showed much wider fault widths than predicted from simple models. Active research is ongoing to understand better the role of phase transformations in deep earthquakes.

3. CORE DYNAMICS AND GENERATION OF THE GEOMAGNETIC FIELD

The last few years witnessed significant progress in the understanding of the origin of magnetic field generation in the Earth's core. The first successful modeling was made in U.S.A. and in Japan in which both the equation of motion of a rotating viscous fluid and the electromagnetic induction equation are simultaneously solved to show the generation of a nearly dipole magnetic field (Glatzmaier and Roberts, 1995, 1997; Kageyama and Sato, 1997). The driving forces in these models include both thermal and chemical buoyancy forces, the latter being due to the solidification of nearly pure iron from iron-rich alloy. The important effects of the inner core are also noted in these models. These models were able to show a stable nearly dipole magnetic field, but some instabilities causing reversals of magnetic field were also seen. One of the important outcomes of this type of model is the prediction of a "superrotation" of the inner core as a result of magnetic coupling between outer and inner cores due to a strong toroidal field (Glatzmaier and Roberts, 1995). "Superrotation" of the inner core may also be attributed to viscous coupling.

Observationally, one of the most fascinating observations is the suggestion that the virtual geomagnetic pole (VGP: the pole of magnetic dipole field projected to the Earth's surface) follows specific paths during the reversal. This notion was inferred from the analysis of magnetic records in sediments, and the results show that the VGP follows a band in the Earth along which seismic-wave velocities are anomalously high at the bottom of the mantle (Laj *et al.*, 1991). This suggests that the temperature anomalies at the core–mantle boundary caused by mantle convection may influence the convection pattern in the outer core that in turn causes the variation in magnetic field (Kuang and Bloxham, 1997).

INTRODUCTION

Developments in the inertial-controlled fusion (ICF) program occurring in the mid to late 1990's have raised expectations that ignition of an ICF pellet in the laboratory may be demonstrated as early as 2005.

1. OVERVIEW OF INERTIAL CONFINEMENT FUSION (ICF)

The basic physics principles of the inertial-confinement fusion concept are described in detail in the original article. As a brief reminder of the concept, recall that the objective is to implode a small pellet containing deuterium (D) and tritium (T), heavy isotopes of hydrogen, to high enough density and temperatures that a substantial fraction of the fuel nuclei undergo fusion reactions and yield bursts of energy. Calculations predict that the fusion energy release in this process can be of the order of 10^2 times the energy driving the implosion. The ratio of released energy to driver energy is called gain. If high-gain ICF can be demonstrated, then it raises hopes that it might be further developed for use in civilian electric-power generation.

To achieve the conditions for high-gain ICF, the outside surface of a pellet of about 1 mm diameter that encloses a layer of cryogenic DT fuel on the shell's inner surface is irradiated by an intense (10^{14} to 10^{15} W/cm^2) energy pulse from a directed energy source, such as a laser. The energy deposition on the pellet surface causes it to ablate and heat, become a hot plasma, and blow away from the surface at high velocity. Pressures of tens of megabars created by the hot ablating plasma surface material drives the remaining shell and interior fuel inward, compressing the DT fuel to over 10^3 times solid density. The driver pulse characteristics, and hence the ablation pressure, are staged such that the bulk of the compressed fuel remains on a low isentrope (dense but cold material) except for a small fuel region in its center. The drive pulse is shaped in time so that the central region, called the ignitor, is heated to temperatures of about 10 keV. This configuration is shown schematically in Fig. 1. If the hot-spot density-radius product is high enough (>0.3 g/cm) to stop the fusion-produced alpha particles at this temperature, then self-heating from the nuclear fusion reactions will initiate a fusion "burn" front that propagates outward throughout the main fuel volume. If all this is done properly, the energy yield of the explosion will greatly exceed the incident energy, yielding net energy. Although most ICF research to date has used a large laser driver, in principle, particle beams from accelerators could also be used.

Tables summarize constraints on drive symmetry, hydrodynamic stability requirements, and ignition parameters. [From LLNL (1995).]

proaches to ICF. When the driver energy beam directly irradiates the pellet, the ICF approach is called "direct-drive." If the driver energy first strikes high-Z material inside of an enclosure, a hohlraum, that converts the beam energy into intense x rays that subsequently strike, ablate, and implode a pellet, the approach is called "indirect drive," "x-ray drive," or the "classified approach." There was a major declassification and disclosure of the x-ray drive approach to ICF in 1993. Most of what follows is a description of the

x-ray drive approach that was omitted in the original article because of classification restrictions, along with more recent advances.

There has also been a significant shift in the programmatic rationale for ICF since 1993. Most of the funding for ICF research in the United States comes from the Department of Energy's defense programs, ostensibly as a laboratory means to gain general information related to nuclear weapons design, operation, and effects. With the breakup of the Soviet Union and the advent of a comprehensive nuclear test ban, the ICF program has become a key component in the U.S. stockpile stewardship maintenance program (SSMP) in the mid-1990's. The purpose of SSMP is to maintain a nuclear deterrent capability in the absence of underground nuclear testing.

2. PRINCIPLES OF X-RAY DRIVE

The x-ray drive approach has actually been the field's principal effort since 1976, although little was known about it in the general scientific community because of U.S. Department of Energy (DOE) secrecy restrictions. The formerly classified information release, combined with recent advances in the scientific basis of the ICF research program and in driver and target fabrication technologies, has raised expectations that an x-ray–driven ICF target could achieve ignition in the laboratory in the not too distant future. A comprehensive review of the development of x-ray drive ICF approach can be found in Lindl (1995).

The distinctive element of x-ray drive is the hohlraum, which is a radiation-filled enclosure made of high-Z material (typically gold) that surrounds a pellet (also known as a 'capsule'), such as depicted in Fig. 2. Laser beams enter the hohlraum by focusing through small entrance holes. Copious x rays are produced where the beam spots strike the interior hohlraum walls. Most x rays are absorbed by and heat the remainder of the hohlraum walls, which in turn, reradiate x rays forming a bath of x rays with an equilibrium distribution. Typical beam–to–x-ray energy conversion efficiencies are reasonably high (70% to 80%). Laser beams are usually arranged in two clusters. Hohlraums are usually cylindrically shaped with an entrance hole in each end cap to accept the beam clusters. The optimal hohlraum design depends upon details of the driver type and pellet design. The beams are arranged to strike the walls such that the x-ray flux falling on the pellet surface is a uniform mixture of x-rays emitted directly from the laser spots and the somewhat lower intensity x-ray albedo from other portions of the hohlraum. The exact beam placement required to achieve the required uniformity and symmetry for high-convergence ratio implosions is an area of active research.

The pressure P_{a} applied at the ablation surface of the pellet is what determines the implosion dynamics of an ICF pellet, whether that pressure be generated by direct-drive or indirect-drive process. The ablation pressure accelerates the remaining shell material inward at a velocity given by the spherical version of the rocket equation, $V_{\mathrm{imp}} = V_{\mathrm{pl}} \ln(m_0/m)$. Here m_0 and m are respectively the original and final mass/surface areas of the pellet shell. The velocity of the plasma ablating away from the pellet, V_{pl}, is given by $V_{\mathrm{pl}} = P_a/[dm/dt]$).

X rays are well suited to generation of high ablation pressures because they deposit their energy directly into the high-density regions of the pellet shell. Dense material deposition results in a higher mass ablation rate (dm/dt) and an ablation velocity that is lower and better matched to the peak efficiency point (where $V_{\mathrm{imp}} \approx V_{\mathrm{pl}}$) of the rocket equation. X rays inside a hohlraum can be characterized by a blackbody temperature, at least within the relevant wavelength regime containing most of the energy. The x-ray intensity impinging on the ablation surface is given approximately by the relation $I_{\mathrm{a}} \approx T_{\mathrm{r}}^4$. By way of calibration, a hohlraum temperature of $T_{\mathrm{r}} = 300\,\mathrm{eV}$ has the equivalent x-ray intensity of about $I_{\mathrm{a}} = 10^{15}\,\mathrm{W/cm^2}$.

For typical ignition target designs, the effective radiation temperatures are in the range 225 to 300 eV. The high-temperature limit is set primarily by the need to keep incoming laser-beam irradiances low enough to avoid stimulating parametric instabilities in the hohlraum plasma. The low-temperature limit comes from the need to achieve the minimum shell velocity for ignition, which is about $3 \times 10^7\,\mathrm{cm/s}$. Here the consensus is that the pellet shell in-flight aspect ratio ($\mathrm{IFAR} = R/\Delta R$) is limited to 30 or less (i.e., this is the thinnest feasible shell) because of excessive hydrodynamic instability.

Capsules need to converge in radius by a factor of 25 to 35 in order to form the small hot-spot region needed to ignite the pellet at peak compression. For a pellet to converge this far and remain spherical requires x-ray fluxes uniform to within 1 to 2%. x-ray uniformity improves with larger hohlraums for a given pellet size, but with a loss of efficiency. Alternatively, optimal placement of beam deposition patterns and careful balance between them can reduce x-ray asymmetries inside a smaller hohlraum.

In addition to good overall x-ray symmetry impinging on the pellet surface, the pellet shell must resist excessive hydrodynamic instability. One of the most critical regions for hydrodynamic instability in indirect-drive pellets is at the inner surface of the main fuel. This is because hydrodynamic instability will tend to mix cold dense fuel into the hot-spot region, cooling it and quenching ignition. The most important factor affecting inner-surface mix is the initial inner-surface roughness of the fuel layer. The upper limit for the inner-surface roughness of the cryogenic DT in typical NIF (National Ignition Facility; see Sec. 4) ignition target designs is about 1 μm when a CH ablator shell is employed, and a factor of two or three higher if a beryllium ablator shell can be used. Hydrodynamic instability causing mix is fed by areal mass nonuniformities. Beryllium is a more tolerant material than CH because its density is lower so that the effect of a given roughness is reduced. Also, a Be ablator shell would be about twice as thick as a plastic (CH) shell, which further reduces the growth rate of the hydrodynamic instability that leads to mix.

Although there is a small loss of efficiency in the process of converting the driver energy into x rays, x-ray drive has a number of potential advantages over the direct drive approach.

1. The pellet finds itself immersed in an x-ray bath that tends to be naturally uniform on account of the broad pattern of the x-ray emission process plus absorption and reradiation by the hohlraum walls. The x-ray emission is relatively insensitive to nonuniformities in the driver beams and, to some degree, to the geometric pattern of incoming beam clusters.
2. X rays penetrate and directly deposit their energy in the vicinity of the pellet ablation surface ($\sim 10^{24}$ electrons/cm^3), which is a few times solid density. This is a more efficient process than the case of direct laser irradiation in which initial laser-light absorption occurs at much lower densities (near or below the critical density, where the laser-light frequency equals the plasma frequency, $\sim 10^{22}$ electrons/cm^3 for 0.35-μm light), requiring the energy then to diffuse up a density ramp to the ablation surface.
3. x-ray deposition creates a softer density gradient in the vicinity of the ablation region that reduces the shell's susceptibility to hydrodynamic instability over that of the direct-drive case.
4. The principal proponents of the x-ray approach, DOE weapons laboratories, have considerable experience, infrastructure, and data base upon which to draw in this area.

This is not to claim that the x-ray ICF approach is ideal or a sure thing. For example, only about 5% of the driver energy actually ends up as useful hydrodynamic implosion energy. This is a relatively inefficient use of high-quality energy from the driver beam. The losses take the form of direct conversion loss of beam energy into x-rays, loss of x-ray energy out the holes in the hohlraum and by reabsorption in the hohlraum walls, and waste heat carried away by the ablating plasma.

Scale sizes of plasmas generated inside a hohlraum can be large, creating a favorable environment for laser parametric instabilities, such as Brillouin or Raman backscatter instabilities. Sizable levels of backscatter would reduce beam energy available to generate x rays and thereby lower efficiency. Avoidance of parametric instabilities tends to cap the maximum laser-beam irradiances that can be utilized.

Finally, there always exists a small residual asymmetry in the x-ray albedo falling on the pellet surface due to the beam deposition geometry. Although the x-ray radiation pattern falling on the pellet is made nearly spherically symmetric by multiple absorption and reradiation of x rays by the hohlraum walls, there can still be enough of a residual asymmetry to affect the implosion symmetry adversely. Excessive asymmetry can seed hydrodynamic instabilities during pellet implosion that prevent formation of a small ignitor region, which, in turn, would increase the fuel needed to be brought to 10 keV and, consequently, the driver energy required for ignition.

For energy applications, the presence of extraneous mass, particularly high-Z materials typically used in hohlraums, is a practical disadvantage. This is because some of the accumulated material from the millions of capsules exploded in an energy reactor will become activated by the fusion neutron flux and must be extracted and disposed of.

Experiments on Nova and elsewhere, as well as computer simulation projections, have demonstrated that most of these potential problems can be averted or made tolerable, and that current x-ray–driven pellets designed for use in the NIF are likely to reach ignition yields.

In spite of the advantages of the indirect-drive approach, direct-drive research is also being pursued vigorously. If direct-drive ICF can be demonstrated, then it might permit ignition and high gain with lower-energy (smaller) drivers, since direct drive does not have energy losses associated with the conversion to x rays and other hohlraum losses. Direct-drive pellets would be simpler in design and cheaper, again since they do not require a carefully crafted hohlraum. Therefore, direct-drive targets are more desirable for energy reactor applications. Since either approach may yet encounter formidable, but presently unknown, problems as they scale up into new parameter regimes, the current ICF program strategy is to pursue both vigorously until it is clear which is superior.

3. CURRENT STATUS OF ICF RESEARCH

3.1 Laser Facilities

Two new ICF-laser facilities designed to pursue the direct-drive ICF approach, under construction in 1993, have been completed and put into operation. The Omega glass laser, at the University of Rochester's Laboratory for Laser Energetics, underwent a complete upgrade to deliver over 40 kJ of UV (0.35 μm wavelength) in each nanosecond-duration pulse in sixty uniform, balanced, and flexible beams. Figure 3 shows a photo of the Omega Upgrade target chamber. Although Omega Upgrade was designed primarily to do integrated direct-drive pellet implosion research, it is also being used to investigate aspects of x-ray–drive physics in preparation for ignition experiments on the NIF. An overview of the Omega Upgrade experimental program may be found in Soures *et al.* (1995). The other new laser facility, Nike, is a relatively small (4 kJ) krypton-fluoride gas laser built at the Naval Research Laboratory. Nike was designed with excellent beam-smoothing features to allow precision planar-geometry hydrodynamic-instability experiments that may help determine the upper yield limit of direct-drive pellet implosions.

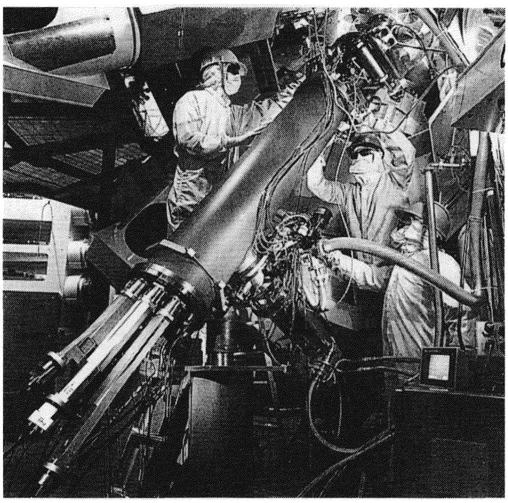

FIG. 3. Omega Upgrade target facility at the Laboratory for Laser Energetics, University of Rochester [From University of Rochester (1996).]

3.2 Target Experiments

The U.S. ICF program has made significant progress in reducing uncertainties in most technical areas required for ignition. Experiments on the Nova laser at Lawrence Livermore National Laboratory (LLNL) have provided a better physical understanding of ignition physics, especially those that may affect target performance with the NIF. The status of some of those investigations is provided in the following.

Currently, gas-filled hohlraums are the baseline targets for use on NIF. The purpose of the gas is to impede the flow of plasma from the hohlraum wall into its volume, thereby reducing the environment for parametric instabilities of the incoming beams. Early Nova experiments indicated levels of laser light backscattered from instabilities and dynamics shifts in beam pointing inside hohlraums large enough to affect adversely the x-ray drive effectiveness. It was conjectured that these effects resulted from high-intensity peaks in the fairly nonuniform Nova beams. Beam-smoothing techniques, such as use of phase plates, and an active beam-fluctuation averaging technique, such as smoothing by spectral dispersion (SSD), were applied to Nova's beams in 1996. Experiments and modeling then confirmed that use of smooth beams largely eliminated these potential problems and brought about a corresponding rise in x-ray radiation temperature and symmetry. These favorable results scale to expected NIF conditions according to current theory and models.

The Omega laser at the University of Rochester has also been used to do precision hohlraum x-ray–drive experiments. Excellent agreement was obtained on Omega with equivalent Nova experiments and LASNEX calculations (Decker *et al.*, 1997). Omega has also been used to test beam configurations planned for the NIF facility. About half of Omega's 60 beams have been arranged into a similar geometry to the NIF point-target design, i.e., two outer and two inner rings of beam irradiation spots inside the hohlraum. Experiments to exercise precise temporal and spatial control over the symmetry of x-ray emission by use of beam delays and pulse shapes were performed. Again good agreement between simulation and experiments was found, showing that similar beam phasing on NIF should provide adequate drive symmetry for ignition implosions.

3.3 Predictive Capability

A key component of successful extrapolation from Nova to NIF, and from NIF to a high-yield facility, is possession of reliable predictability through an accurate computer simulation capability. Most of the experimental results are used either to validate predictive codes, or to help add or correct the physics models required to do so. Increasingly, it has been found that two-dimensional (2D) codes are not sufficient to model implosion dynamics and that three-dimensional (3D) simulations are needed. In the mid-1990s, a radiation-hydrodynamics code, HYDRA, which includes full fusion burn physics, was developed. HYDRA is now routinely used for modeling ICF capsules. In particular, the surface-finish smoothness requirements for the inner surface of the deuterium-tritium ice layer in NIF ignition targets have been studied. HYDRA showed that a DT-containing shell made with a plastic ablator can tolerate up to 1-μm rms DT layer roughness, whereas the corresponding shell made of beryllium ablator can tolerate up to three times more roughness.

3.4 NIF Ignition Target Point Design

The baseline ignition capsule (pellet) for use on the NIF has a cryogenic DT-ice shell surrounding a central DT-gas region that resides inside a gas-filled gold hohlraum, as depicted in Fig. 4. The DT ice is surrounded by either a plastic or a beryllium shell that both forms a vessel to hold the DT and acts as the ablator material. With an expected NIF input of 1.8 MJ in a 500-TW pulse shaped as shown in Fig. 4, yields of order 15 MJ are predicted. This leaves about a safety margin of close to 10 above the ignition level for nonideal performance. There are over a dozen target designs that reach ignition levels, most of which have moderate robustness for nonideal behavior. As mentioned previously, the most sensitive parameter that can spoil performance is the surface finish of the inner DT-ice surface, which affects the level of hydrodynamic instability causing mix in the hot-spot region. Since significantly higher DT-ice roughness is tolerated with beryllium ablators than with plastic ablators, considerable research is being

performed on fabricating suitable Be shells. A more complete description of ignition target design can be found in Haan *et al.* (1995).

3.5 Target Fabrication

Plastic shells are the mainline target for NIF ignition because their fabrication and characterization has been demonstrated. The relaxed specifications on surface finishes of cryogenic DT layers in Be targets have motivated efforts to develop the means to fabricate Be shells with the proper uniformity. Both machining and sputter-coating methods are being evaluated for this purpose. Although good progress has been achieved, the fabrication of beryllium shells with both sufficient uniformity and a means to load them with DT fuel needed further development as of 1998. It is expected that beryllium will indeed become the *de facto* ablator material, with plastic kept as the fallback option.

4. NATIONAL IGNITION FACILITY

Among the facility proposals under consideration in the early 1990s was a "Nova Upgrade," the purpose of which was to increase the existing 10-beam Nova laser's energy to a level that could approach pellet ignition. Subsequently, a very large glass laser facility of this type, called the National Ignition Facility (NIF), was designed and approved for construction in the United States. Figure 5 shows a sketch of the NIF as it is expected to look when completed. The new name reflects both the fact that the NIF is an entirely new facility and that it is being viewed as a national resource for use by all research participants in the U.S., and perhaps worldwide. The NIF is viewed as a key element of the U.S. stockpile stewardship management program. An ignition facility very similar to the NIF is also planned for construction in France.

29 May 1997 was the groundbreaking for the National Ignition Facility at Lawrence Livermore National Laboratory. When operational in the 2005 time frame, NIF will be the world's largest laser, about twenty times more powerful than Nova, the LLNL laser it is replacing. The heart of the system is an Nd laser with 192 beams that will produce in excess of 1.8×10^6 J of ultraviolet (0.35 μm) laser light energy in 3 ns (about 500 TW).

The NIF was designed to be very flexible, incorporating beams with excellent uniformity, interbeam balance, and pulse shaping. It was also constructed to allow relatively easy reconfiguration into direct-drive geometry facility. The size (energy) of the NIF was chosen to

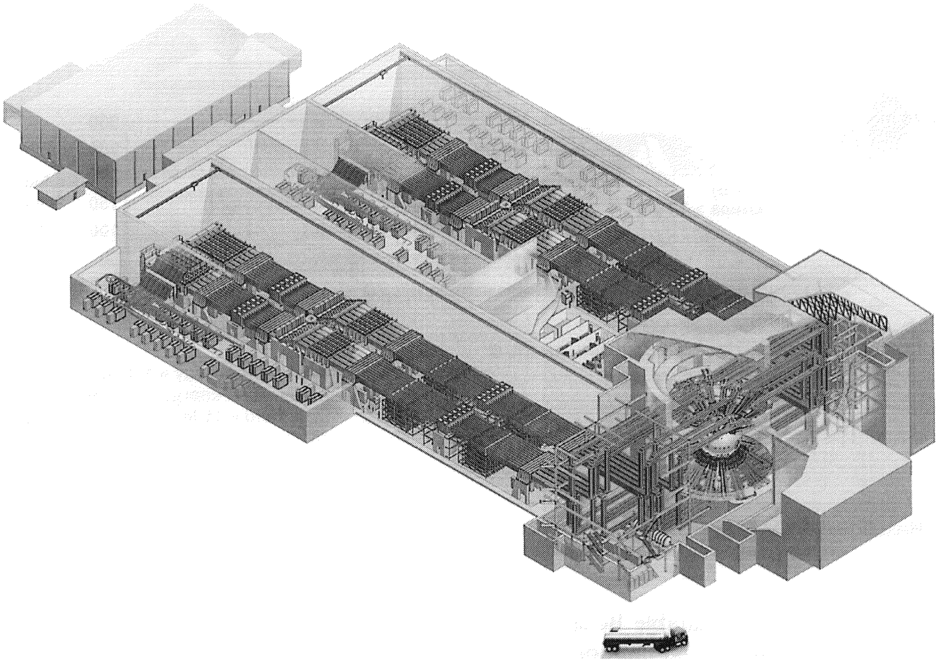

FIG. 5. The National Ignition Facility (artist's sketch courtesy of LLNL).

have a likelihood to achieve ignition level yields, yet small enough to contain costs. The completed facility is expected to cost about 1.2×10^9 (1997) dollars, including the laser, associated experimental and target fabrication facilities, and infrastructure. The NIF will consist of about 8000 large (over 1 ft^2) optical components and more than 30 000 smaller ones. The operational lifetime of the NIF is expected to be about 15 years.

Although located at LLNL, the NIF was designed, built, and operated as a national facility through a partnership with Los Alamos National Laboratory, Sandia National Laboratories, and the University of Rochester Laboratory for Laser Energetics, in addition to LLNL. General Atomics, Inc., is a partner in developing the target fabrication technology to be used in NIF experiments.

The NIF is scheduled to be completed in several phases, with the first set of eight beam lines ready for testing in about 2001. Beamlet, a prototype of one NIF beam, began operating at LLNL in 1994. The Beamlet prototype was necessary to validate the laser architecture used in NIF, which is much different from previous-generation lasers.

The light from NIF's beams will be directed into a 10-m-diam spherical target chamber and focused onto the relatively small (millimeter) targets. The target chamber will be loaded with sophisticated diagnostic instruments to measure the performance of the pellet performance. The entire NIF facility is being designed to accept either indirect-drive geometry, in which the beams enter the chamber primarily in clusters on the top and bottom of the target chamber, or direct-drive geometry, in which the beams enter the chamber more symmetrically. Although the indirect-drive configuration will be implemented first, the system will be reconfigured should direct-drive experiments at Omega Upgrade prove more promising.

4.1 Science-Based Stockpile Stewardship

Establishment of the science-based stockpile stewardship (SBSS) program, a subset of the comprehensive stockpile stewardship maintenance program (SSMP), was a consequence of the cessation of the cold war and President Clinton's order for a moratorium on U.S.

nuclear weapon testing in 1993. (Subsequently, in 1996, the U.S. and over 90 other nations signed a Comprehensive Test Ban Treaty.) The SBSS represents DOE's strategy to address the challenge of retaining nuclear capability in a test-free environment. The 1994 National Defense Authorization Act called for "a stewardship program to ensure the preservation of the core intellectual and technical competencies of the United States in nuclear weapons." The SSMP is directed to do this in a manner consistent with the broad arms-control and nonproliferation goals of the United States and most other nations.

The SBSS is structured to maintain a continuing capability to anticipate, detect, and correct problems related to aging of the nuclear stockpile. In addition to accumulating detailed knowledge about nuclear technologies, understanding of high–energy-density physics, reliable computer simulation capability, and the like, it requires that there continue to be a number of excellent scientists and engineers trained and knowledgeable in weapons related areas.

The role that ICF, and NIF in particular, play in the SBSS program is to explore the physics of matter and radiation at high energy density and the physics of thermonuclear fusion in a laboratory setting. Ignition of an ICF pellet in NIF is a major goal. The goals of SBSS and NIF are also fully consistent with the goals of both the defense and energy ICF applications. Many people believe that it was only the confluence of favorable events, such as of the end of the cold war, test bans, and nonproliferation policy, concurrent with readiness of glass-laser technology and advanced and positive ICF research results, that allowed the NIF to be authorized in the tight federal fiscal environment of the mid-1990s.

5. HEAVY-ION DRIVER DEVELOPMENT

Although the most advanced and utilized drivers for ICF pellet implosion research to date are lasers, there has been some progress in developing particle-beam accelerators for ICF driver use. Particle-beam driver concepts currently assume use of the x-ray drive approach (although direct-drive schemes are also possible in principle). Particle-beam energy is first converted in a hohlraum into x rays that, in turn, irradiate and drive pellet implosions. The technical feasibility of the development of a heavy-ion induction linear accelerator continues at Lawrence Berkeley Laboratory, but at a slow pace due to low funding levels ($\$7 \times 10^6$ level in FY97 out of a total ICF funding of $\$250 \times 10^6$). The reader is directed to the original article for further details and references that describe several heavy-ion driver approaches.

6. *Z*-PINCH DRIVER

There has been a program, from the early days of the ICF program, to determine if electric-pulse–power devices could be used as a driver. Pulse-power devices store large amounts of electrical energy in capacitor banks or inductive units and use switching elements to discharge the electrical energy rapidly into a load. Discharge-pulse parameters are in the tens of nanoseconds time scale with voltages in the multimegavolt range and with multimegampere currents.

In the 1970s, the approach used was to generate an electron beam in the load, frequently called a diode, to drive the pellet implosion. The electron-beam approach was dropped when the multi-MeV electrons from the driver beam were found to penetrate and preheat the pellet interiors to unacceptable levels. In the 1980s and early 1990s, the diodes were configured to have reverse polarity, and efforts were shifted to accelerating light ions (hydrogen or lithium) for pellet driver application. After encouraging initial results, light-ion driver ICF development stagnated for a number of years because no way was found to focus the beam to sufficiently high energy densities. This resulted in hohlraum temperatures much too low to be useful. The light-ion–beam accelerator approach was essentially abandoned in the mid-1990s.

In 1996, Sandia National Laboratory made a major advance in the generation of x rays with a different pulse-power approach. They rejuvenated and refined an old pulse-power device, called a *Z*-pinch, to generate x rays directly, without use of a particle beam inter-

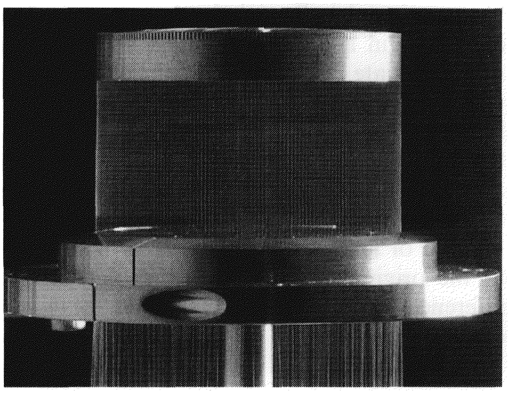

FIG. 6. Wire array load for Sandia *Z*-pinch x-ray source. The diameter of the cylindrical array of 300 tungsten wires is about 2 cm. The pulse-power voltage is applied across the top and bottom support rings. (Courtesy of Sandia National Laboratory.)

mediary. This *Z*-pinch consists of a wire array load that gets vaporized, is made into a plasma, and is pinched to high density and temperature by the magnetic field from the huge currents flowing through it. In the process, the pinched plasma emits copious x rays. Sandia produced a record 1.9 MJ of x-ray energy in a 200-TW pulse with the 300-wire array load pictured in Fig. 6. Using this x-ray source, they produced a 130-eV black body temperature inside of a 2.5-cm-diam hohlraum in 1997. While the hohlraum temperatures demonstrated are still at least a factor 2 to 3 too low to drive ignition-level pellets, the results are viewed as encouraging. Sandia proposed to build a larger version of this device, called X-1, that might be used for ignition-level experiments in the late 1990's. A *Z*-pinch ICF driver is best suited for defense applications that require single-shot capability (e.g., one shot per day or less), since the *Z*-pinch load region is destroyed with each firing. It is difficult to imagine a *Z*-pinch being compatible with the high repetition rate needed for a civilian power plant.

7. ALTERNATE CONCEPT: FAST IGNITOR

If inefficiencies and waste heat could be eliminated, high-gain fusion yield could be achieved with as little as 100 kJ energy input. This is approximately the energy required to compress low-temperature main pellet fuel to the high densities required to support propagating fusion burn. What is then needed, in principle, is only a few tens of kilojoules delivered to the central small ignitor region that raises its temperature enough to initiate propagating fusion burn. In conventional approaches (direct and x-ray drive) ignition is achieved by carefully programming in a set of shocks converging though the cold, dense main fuel region that coalesce at the right instant to heat and ignite the central region. This is a rather inefficient process, as only a small fraction of the shock energy transfers to the ignitor, even if done optimally.

The fast-ignitor concept would employ an ultrahigh-intensity laser to burrow through the corona surrounding the compressed fuel and deliver energy directly to an ignitor region in the form of energetic electrons, as depicted in Fig. 7. By way of an example, to heat a DT ignitor region of density 300 g/cm^3 to about 10-kV temperature using energetic electrons requires focal intensities of at least 10^{20} W/cm^2 with 1-μm light in a pulse duration of 1 ps (i.e., 10 kJ). Any laser–matter inefficiencies will increase the associated laser requirements. A laser prepulse of order 10^{19} W/cm^3 is needed over a few tens of picoseconds to create the immense pressures required to push the cold fuel aside and form a low-density channel through which the much more intense ignition pulse can be delivered.

The fast-ignitor concept is considered to be very speculative approach, since it requires specific (favorable) physics behavior through large extrapolations in unexplored, highly nonlinear portions of parameter space. Nonetheless, if it can be demonstrated to work, the costs to achieve high-yield ICF and the engineering requirements for the reactor chamber plummet and the variety of driver options decrease.

A petawatt laser (10^{15} W) has been developed at LLNL to test some of the physics basis of the fast-ignitor concept. The petawatt laser produces about 1 kJ of 1.053-μm light at irradiances above 10^{21} W/cm^2 with a pulse length in the 1-ps regime. The laser starts with short chirped pulses (broad bandwidth) that are stretched to about 1-ns duration with a dif-

fraction grating. The stretched pulse length is well matched for efficient amplification using a slightly modified Nova amplifier chain, followed by recompression of the pulse duration down to the picosecond regime using large recompression diffraction gratings. Proof-of-principle experiments of the critical fast-ignitor physics issues began in 1997 using the petawatt laser. A more complete description of the fast ignitor concept may be found in Tabak (1994).

8. INERTIAL FUSION ENERGY

Efforts directed specifically to produce a civilian energy source based on ICF, called inertial fusion energy (IFE), continue, but constitute a minor portion of the total ICF program. However, the essential stage of demonstrating ICF ignition in the laboratory is common to both energy and defense applications; hence the ICF program resources have been concentrated on this goal. A critical requirement for civilian energy use of ICF is a driver that is capable of being cycled with a repetition rate of about 1 shot/second with good efficiency and reliability, long lifetime, and compatibility with a reactor environment. Heavy-ion accelerators appear to be capable of meeting these requirements. Two laser technologies that might potentially satisfy the energy driver requirements, high–repetition-rate KrF-gas laser and laser-diode–pumped glass lasers, are also being investigated at low levels.

9. PROGNOSIS

The inertial-confinement fusion program has progressed to the point where the scientific basis and technology for the next major step is in place, that of demonstrating ICF ignition in the laboratory. When complete in about 2005, the National Ignition Facility will have this capability. Although the primary impetus for the program is defense related, this phase is also necessary for the development of inertial fusion as an electrical power source. Obviously, the next decade will be an exciting and telling period.

INTRODUCTION

In the 1990s there has been significant progress in the development of the tokamak concept and serious study by an international research group [the International Thermonuclear Experimental Reactor (ITER) team] on the feasibility and design of an experiment to demonstrate fusion power production. In this Addendum we present an overview of the status of tokamak research in relation to achieving this goal.

1. POWER-PRODUCING TOKAMAK EXPERIMENT

1.1 Magnetic Field

Recall that a tokamak is a toroidally shaped plasma in a magnetic field as shown in the schematic diagram of Fig. 1. Its cross section is shown in Fig. 2, with dimensions envisioned for a 1500-MW power-producing experiment. The dominant magnetic field is in the toroidal direction and is established by toroidal field (TF) coils that poloidally loop the plasma. A smaller, poloidally directed magnetic field arises from toroidally directed current flowing in the plasma itself and toroidal currents flowing in poloidal field coils that are outside and parallel to the plasma (currents external to the plasma control the shape and position of the plasma). All these currents produce magnetic field lines that circulate in the toroidal and poloidal directions and form magnetic flux surfaces. The q value (a parameter that will be frequently referred to) of a surface is the number of times a field line circulates in the toroidal direction in one poloidal circuit. The surfaces are represented by closed surfaces in Fig. 2.

1.2 Central Solenoid

The central solenoid is used to supply the toroidal voltage that sustains the plasma current. The voltage arises from the time rate of change of the entrained magnetic flux in the coil of the central solenoid. However, without other current drive methods being imposed, the establishment of the plasma equilibrium and the sustainment time of the discharge are limited by the time integral of the emf that is obtained by reversing this magnetic flux. This time is expected to be about 1000 s in a fusion-producing plasma.

1.3 Fusion Burn

Charged particles are trapped in continuous spirals that closely follow the entrapped field lines. This containment allows the particles to be heated to temperatures where fusion reactions occur. For a deuterium-tritium mixture, this temperature is in the range 10 to 25 keV where we use temperature in units of energy (where $1\,\text{eV} = 1.16 \times 10^4\,\text{K}$). When deuterium and tritium fuse ($d + t \Rightarrow {}^4\text{He} + n + 17.6\,\text{MeV}$), the 14-MeV neutrons leave the plasma and are absorbed by the walls. Their energy is to be used to produce steam that drives an electrical power plant. In addition the neutrons are needed to breed tritium (tritium is radioactive with a half-life of 12 years and is available only in limited amounts from fission reactors). Hence it will be necessary to surround a fusion reactor with a lithium blanket (see FUSION TECHNOLOGIES) to breed tritium ($n + {}^6\text{Li} \Rightarrow t + {}^4\text{He} + 4.8\,\text{MeV}$; $n +$

$^7\text{Li} \Rightarrow t + {}^4\text{He} + n' - 2.5\,\text{MeV}$). The 3.5-MeV charged alpha particles (^{4}He) should be retained in the tokamak and their energy transferred to the background plasma by collisions. Then, even without external heating, a "burn" is established, whereby the plasma fuel remains hot while losing energy by bremsstrahlung, atomic radiation, and convection of heat to the "cold" solid walls. Ignition occurs when the fusion-produced alpha particles supply the required heating instead of an external source.

1.4 Divertor

Figure 2 also illustrates a single divertor configuration where there is a special magnetic flux surface called the separatrix (the one where the poloidal field lines appear to cross). Field lines beyond the separatrix (the scrape-off layer) impinge on structure called divertor plates designed to handle large escaping heat loads (charged particles that diffuse outside the separatrix strike here). Gas formed from the recombined plasma is to be pumped away from the surrounding divertor chamber into a closed tritium-recovery system.

2. OPERATION OF A BURNING PLASMA

2.1 Lawson Condition

In order for fusion reactions to be thus sustained, the confinement properties at fusion temperatures must satisfy the Lawson criterion, $n\tau_E \approx 2 \times 10^{20}\,\text{m}^3\,\text{s}$ (here n is the d-t ion density and τ_E the overall energy lifetime). The energy lifetime is determined by transport arising from particle collisions and plasma-induced short-wavelength turbulence. At fusion temperatures, the density is limited by magnetohydrodydamic (MHD) stability. This sets a limit on the parameter β, the ratio of the average pressure (the particle density times the temperature) to magnetic field pressure. In standard tokamak operation, where the current density is largest in the plasma's center, there is a further MHD limitation that prevents the q value (which is inversely proportional to the current density) from being too much less than unity. In the standard case the β is limited to about 5%. In addition there exists a less well understood empirical density limitation, perhaps associated with charged-particle recombination, known as the Greenwald limit, which seems to limit the maximum density to a level proportional to the mean current density of the discharge.

2.2 Magnetic Field Limits

Another limitation is set by the magnitude of the magnetic field that can be imposed. With pulsed operation ($\sim 10\,\text{s}$), TF coils with about a 20-T peak field (producing a 13-T field at the plasma center) have been designed. However, superconducting magnets are generally considered to be needed for a fusion experiment designed to operate in quasisteady conditions of order 1000 s. Then peak fields are limited to 12 T, which allows a 6-T field at the plasma center.

2.3 Empirical Scaling

The energy lifetime of a typical tokamak discharge is uncertain as it is primarily governed by incompletely understood turbulent processes. Thus the extrapolation of tokamak parameters to larger-size reactor regimes is typically based on empirical scaling to the experimental database, obtained from many different installations. A reasonable fit to many experiments is achieved by assuming that the energy lifetime is proportional to algebraic powers of the physical parameters defining the experiment (such as plasma current, magnetic field, plasma heating rate, etc.), with the value of each power the same for all the experiments. A general conclusion from this procedure is that confinement improves with increasing plasma current but degrades with increasing heating power. When this law is applied to an ignition experiment, the extrapolated lifetime is compatible with achieving ignition, but with some uncertainty due to the variance in the data.

2.4 Heat Load

The dimensions shown in Fig. 2 arise as a result of conforming to the constraints mentioned above. They lead to a total fusion-power production in the gigawatt regime (Post and Uckan, 1992). One fifth of this power (from alpha particles) directly heats the plasma. The heat exhausts on plasma-facing material with a rather modest average power load of about 0.2 MW m^{-2}. However, should most of this heat impinge on the divertor plate, an unacceptable 40-MW m^{-2} heat load would arise.

Operation with a divertor is viewed as essential. It has been found to be extremely important to control the impurities that enter the plasma, to design efficient pumping methods, and to establish the conditions for optimum plasma confinement in the so-called *H*-mode. The *H*-mode of operation improves the energy confinement time a factor of 2 or more compared to an alternative mode of operation, the so-called *L*-mode (see below for further discussion).

A fix to this heat exhaust problem is to radiate away most of the exhaust energy. For example, if 1500 GW of fusion power is being produced, then the plasma is directly heated by the 300 MW in alpha particle production. Roughly 100 MW radiates as bremsstrahlung. Impurity seeding at the plasma edge and diverter throats is required to radiate away about 150 MW so that the remaining 50 MW of heat flux in the escaping plasma allows a tolerable power-density load of less than 10 MW m^{-2} at the divertor plates. Favorable results are now available in several tokamak experiments that demonstrate that the heat load on the divertor plates is indeed reduced by such impurity radiation shielding, in a so-called semidetached mode of operation, while maintaining relatively good purity of the plasma. An important associated issue is whether optimal *H*-mode confinement properties can be achieved in semidetached operation. Most experiments observe confinement degradation, but there have been results that demonstrate, in semidetached operation, confinement properties close to that in typical *H*-mode operation.

2.5 Pumping

Pumping in the divertor region is extremely important in reactor operation. The helium accumulating in the core must be pumped away. Otherwise the burn quenches after ignition is achieved, as helium ash is replacing plasma fuel. Experiments have shown that the ratio of helium to energy lifetime is about 5, and with pumping and *d-t* gas puffing the helium accumulation can be limited to 10% of the plasma density, an acceptable level. The pumping in the divertor system is a principal control of the plasma impurities as well. The density of seeded impurities needs to be peaked near the scrape-off layer but diffuse in the plasma bulk. Experiments have demonstrated that this can be achieved.

2.6 Ignition Physics

There are several intrinsic physics issues associated with achieving ignition and burn. One is the control of the parameters of the plasma. There can be an ignition-induced instability, where once the fusion burn dominates, the plasma heating rapidly increases the plasma pressure. The increased pressure can cause the system to enter unstable MHD regimes where confinement deteriorates or is even lost. The conditions for such excursions are believed to be understood and in principle can be avoided. Ultimately the appropriate operation must be experimentally demonstrated.

Another burn issue is the physics associated with alpha-particle confinement. To achieve burn the alpha kinetic energy must be absorbed by the plasma. It is possible for energetic alpha particles to diffuse to the plasma edge and then embed themselves into the plasma-facing material. It is estimated that a limit of only 5% of the generated energetic alpha particles can be lost in this way if serious wall deterioration is to be averted.

Energetic alpha particles near the edge are primarily lost as a result of complicated motion arising from the presence of toroidal magnetic field ripple resulting from the spacing of a finite number of TF coils in the machine. It has been shown that if only the energetic alpha particles born near the edge are lost, there is a tolerable loss with a reasonable number of TF coils. However, there is still a concern that alpha particles can be fed into the edge region from plasma instabilities. One possibility is that Alfvén-wave instabilities can be spontaneously generated with the alpha particles themselves the instability source. Another possibility is that alpha particles are lost through MHD activity of the plasma, which either directly drives the alpha particles into the loss region or indirectly triggers the Alfvén instability by causing a rearrangement of the alpha-particle pressure profile. Such scenarios, with loss, have been observed in experiments that use energetic particles arising from neutral-beam injection or ion-cyclotron rf heating. In the TFTR tokamak, where up to 10 MW of fusion power has been produced, the alpha-particle–driven Alfvén wave has been observed, but in these cases the observed saturation level is too low to cause significant energetic particle loss. Theory predictions indicate that an alpha-particle–driven Alfvén instability is unlikely to arise for many operating parameters, but it may prevent some otherwise desirable set of plasma parameters from being achieved.

3. PLASMA CONFINEMENT ISSUES

3.1 *H*-mode

Clearly energy-confinement time is a critical parameter in determining the feasibility and design of fusion-power production. The plasma properties can be significantly altered if turbulence conditions are changed. This appears to be the case when there is a transition from *L*-mode to *H*-mode operation. In *H*-mode a pedestal in the temperature appears at the edge of the plasma with a radial thickness typically of an ion orbit width. In this layer there is a flowing plasma with radial shear. A widely accepted explanation of why *H*-mode is established (Itoh and Itoh, 1996), is that the escaping plasma causes a torque to be generated that drives a shearing flow. The shear in turn suppresses fluctuations in the pedestal region by either "ripping" apart the coherence of the fluctuations so that they saturate at a low level, or preventing unstable fluctuations from appearing. It is experimentally observed that a threshold power level is needed to establish an *H*-mode, and this observation is consistent with the hypothesis for the cause of shear flow. The determination of this level is still uncertain; there is no generally accepted quantitative theory, and empirical studies have too much scatter to predict whether, in the reactor operation described above, there is enough power flowing through the edge to establish an *H*-mode. This is an important issue that is to be resolved in ongoing studies.

3.2 Transport Barriers

The studies of the *H*-mode have been crucial in the discovery of new ways to improve energy confinement (Burrell, 1997). It has been found in many tokamaks that by applying torques in either narrow or wide regions of the plasma, by use of either neutral beams or rf sources, transport barriers can be established in the core of the plasma. High temperatures have been established in the central region, with a large drop in the temperature taking place in the transport barrier. It has been further found that establishing this barrier is aided by having a hollow current profile, which leads to a reversed q profile that has a local maximum at the plasma center and a minimum q value, typically ~ 2, further out radially. The thermal barrier is generally established near the minimum-q position. Stability theory indicates that in the region where q is radially decreasing, the strength of the diamagnetic-drift– and magnetic-curvature–driven instabilities (see FUSION, MAGNETIC CONFINEMENT) are reduced. Then the flow shear that is established is enough to stabilize the modes completely. Some experiments report that the residual transport can be explained by transport due only to collisional effects.

The major issue with modes that have hollow current profiles is that they are transient, unless a tailored emf can be applied from auxiliary-current drive methods involving rf or neutral beam sources. It needs to be demonstrated that power requirements for such a drive are compatible with reactor operation.

Another benefit from the hollow current profiles is that they lead to plasmas where a large fraction of the current is in the form of bootstrap current (see FUSION, MAGNETIC CONNEMENT), which does not decay in absence of voltage. If this can indeed be established, then true steady-state operation in a reactor with non-Ohmic current-drive power is feasible as it leads to acceptable power requirements for driving the nonbootstrap current component. Steady-state operation is extremely desirable. It avoids what may be delicate plasma control issues associated with startup and shutdown, as well as thermal stresses associated with repetitive operation that lead to material deterioration.

3.3 Transport Theory

There has been considerable development in theory to achieve transport predictions based on plasma-physics principles. The theories used are still in a post-processing phase, i.e., they explain the temperatures achieved in a large number of experiments but have not predicted the temperature of any experiment before it was performed. One reason is that a theory for energy transport is easier to develop than a theory for particle transport. Hence to determine temperature, a density profile has to be taken from experiment. In addition the transport processes in the core of the plasma are thought to differ from the processes at the edge, and typically the various predictive methods make allowances for less understood edge transport processes either by using experimentally observed temperatures at the edge or by adjusting edge transport coefficients to match empirical observation. As a result many theory-based transport calculations produce good correlation of the predicted and observed energy lifetimes for a variety of experiments (Connor *et al.* 1997). However, when the theories are extrapolated to reactor-type plasmas, significant deviations are predicted. One theory predicts that gigawatt fusion power operation can be expected only if a high edge temperature, 4 keV at the inner edge of the pedestal, can be achieved, while another theory indicates that such fusion power levels can be achieved even with a modest edge temperature. In such a case the former theory would predict a fusion power output that is about a factor of 2 larger than the external heating input, which would give a few hundred megawatts of fusion power when about 100 MW input power is available.

The issue of attaining a predictive theory is of high priority, and tests to resolve existing discrepancies are still in progress. Nonetheless, it is clear that there has been a great deal of basic progress in the understanding of the turbulent transport problem, and we can expect the theoretical reliability of this approach to improve rapidly.

3.4 MHD Considerations

If the plasma's MHD stability characteristics can be improved it can lead to better reactor properties. At a given temperature, a greater density can be achieved, making it easier to satisfy the Lawson criterion. One of the important parameters controlling MHD stability is the plasma shape. Note the vertical elongation and the triangular shape of the outer flux surfaces in Fig. 2. The decreasing pressure profile at the pedestal is a destabilizing effect on the outer part of the surface and is a stabilizing effect on the inner part of the surface. The triangularity allows stronger weighting from the stabilizing inside than would arise without this type of shaping. Then the temperature drop at the pedestal where the H-mode formed can be increased to a limit apparently determined by MHD oscillations known as elms. As one example we note that in 1996 the best bulk confinement parameter $n\tau_E T = 1.5 \times 10^{21}\ \mathrm{m}^{-3}\ \mathrm{s\ keV}$ was achieved in the JT-60U experiment, in part as a result of shape optimization.

There are many experiments that achieve higher β values, but they frequently have MHD fluctuations that reduce the energy-confinement time or cause a disruption where the plasma discharge rapidly disintegrates. One route to a disruption is through a so-called locked mode, where a perturbed wave "attaches" to an imperfection of the stationary magnetic field, which can cause deterioration of the discharge. Locked modes are avoided with a sufficiently large plasma rotation, and hence enough rotation needs to be generated in a fusion power-producing experiment.

There is a great deal of optimism that discharges with reversed q profiles in the center can attain significantly increased β values, particularly when a close-fitting conducting wall is used. However, in this case slowly growing modes still arise on account of the finite wall resistivity. Such modes can in principle be controlled by feedback with low-power sensing circuitry. More experiments on this topic are needed, and appropriate reactor designs still need to be developed.

3.5 Reliability

The demonstration of reliability is another challenge for tokamak operation. In conventional operation, pulsations, such as sawtooth oscillations and elms, are common. Typically the sawteeth arise when the q value of the discharge is somewhat below unity and the pressure profile peaks too strongly within the $q = 1$ surface. The time interval between sawtooth pulses is typically a fraction of the overall current diffusion time (the time interval is of order 100 ms in the larger present-day machines and is expected to be about 1 s in a tokamak like that described in Fig. 2). The pulsation flattens the pressure profile within the $q = 1$ surface, but it also has a beneficial effect of preventing further steepening of the central current profile, a destabilizing tendency. These pulsations generally cause rather small perturbations at the edge so that ordinary sawteeth by themselves are not likely to induce heat-flow problems at the divertor plates. However, in some operations energetic particles induce a change of plasma behavior that causes the sawtooth oscillations to be suppressed for long time intervals. Unfortunately, at times, a giant sawtooth pulse appears that disturbs edge conditions and can even disrupt the entire plasma discharge. Such behavior must be controlled in reactor operation.

The elms, mentioned earlier, are a plasma edge perturbation that cause enhanced heat pulses to outflow at regular time intervals. There is an acceptable type of elm operation, so-called grassy elms, where the pulses are frequent but low level, which leads to heat loads that are readily handled, good global confinement characteristics, and an observed advantageous property of keeping impurities from accumulating in the main part of the plasma. However, elms arise that give larger heat pulses and less favorable plasma confinement. A further difficulty is that a large elm pulse can cause termination of H-mode operation, which will then lead to a significant reduction of the fusion output unless active counter measures to restore H-mode operation are found.

Large disruptions are known to arise in tokamaks, leading to the loss of the plasma discharge. Frequently these disruptions are uncontrolled and are more likely to arise for tokamaks that operate at the limits of acceptable operation. Of concern is that large disruptions can cause damage to plasma-facing wall components due to localized heat deposition, the formation of so-called halo currents where the plasma current penetrates the surrounding conducting wall, and the formation and subsequent wall bombardment of relativistic "runaway" electrons accelerated from the inductive electric field.

Studies are in progress to develop reliable ways that disruptions can be guided to a "soft" landing, where the heat is distributed benignly over the entire surface of plasma-facing walls (for example, from injection of so-called killer pellets, that cause the heat to radiate), and the current in the remaining cold plasma, together with its associated magnetic field energy, is allowed to dissipate on the time scale of a second, a time interval long enough so that the inductively produced electric field is too low to cause runaway electrons.

4. ALTERNATIVE APPROACHES

4.1 Alternative Tokamak Approaches

On the basis of the knowledge known today there is a high confidence level that a fusion power-producing experiment can be designed to operate, at a minimum, in a fusion-power amplification mode where several hundred megawatts of power are produced. A more challenging goal is to achieve, reliably, quasi-steady burn conditions or a high enough energy amplification level to produce gigawatt power levels. Such success requires maintaining optimal tokamak performance (such as H-mode operation, steady alpha-particle heating, limited parameter excursions from pulsations, etc.) in the standard-type discharge discussed above.

Alternative directions of research will proceed either in conjunction with, or as an alternative to, the direct implementation of a fusion power experiment. Perhaps the most exciting development in the mid-1990s is the demonstration that turbulence levels can be dramatically diminished, leading to enhanced confinement, as a result of the combination of plasma flow shear and establishing q profiles that decrease radially over much of the discharge. The future challenge in the operation of this type of discharge is to demonstrate that such conditions can be steadily maintained with modest external power control that extrapolates properly to reactor-size plasmas. The intrinsic bootstrap current in such discharges is expected to be high enough that the power needed to maintain true steady-state reactor operation can be achieved. Significantly, non-inductive current-drive experiments in the Tore-Supra and in other tokamaks have already proven that plasma discharges can be sustained indefinitely, but the needed efficiency is still to be demonstrated.

Future research will also focus on achieving higher plasma pressure operation by implementing conducting-wall stabilization with feedback to control slowly growing resistive wall instabilities. The new methods of obtaining enhanced confinement may also lead to alternative designs for plasma shaping. Other studies are examining whether plasma confinement properties can be improved by increasing a tokamak's minor-to-major radius or major-to-minor radius ratio. Preliminary arguments and data give supportive reasons why such approaches can be beneficial.

There is extensive interest in building an experiment that demonstrates ignition and a short burn, but that does not address long-time reliability issues (Coppi *et al.*, 1994). By using the highest possible magnetic fields, plasmas can be established that are well within intrinsic parameter limits. Hence in such an experiment the likelihood of achieving a proof-of-principle controlled burn is high. Future improvements in the development of large superconducting magnets to the 20-T range would have a dramatic impact on the progress of controlled magnetic fusion. Then long-time burn experiments can be performed at high fields, allowing engineering issues associated with power production to be tested.

Another alternative is to attempt to obtain net fusion-power operation when the *d-t* temperature is greater than the electron temperature. It is significant that such operation characterizes experiments that have achieved some of the highest Lawson parameters in JT-60U, JET, and TFTR and the highest fusion power (16 MW in JET). If the $n\tau_E$ parameter can be increased another factor of 3 to 4 in the former two machines, the condition of a relatively compact reactor operation would nearly be established. There is a problem with maintaining this mode, because as confinement improves the electron and ion temperatures tend to approach each other, and in the process degrade the favorable features of this type of confinement. A novel mechanism known as energy channeling has been suggested, where through the controlled stimulation of rf waves, the alpha-particle energy directly heats the *d-t* fuel rather than the alpha particles primarily heating the electrons (as generally occurs). The technical feasibility of this idea is still under study.

4.2 Other Concepts

The most developed alternative to tokamak research is the stellarator concept (see the original article), where charged particles are confined by the three-dimensional magnetic field established by currents in external coils. This concept is intrinsically steady state; some plasma confinement regimes have been shown to be comparable to similar tokamak confinement regimes, and experiments have been free of disruptions. Of principal concern is that the achieved β values in stellarators are generally lower than in tokamaks, and in most designs a large class of energetic particles are not contained in the magnetic fields. A positive recent development has been the design of so-called quasisymmetric fields, which improves confinement of energetic particles. However, this design still needs to be made compatible with the achievement of reasonably large β limits. Another advantage of a stellarator is its typical property of a radially increasing q profile. This may allow easier access into regimes demonstrating enhanced confinement. A new large stellarator in Japan, the LHD, began operation in 1998, and it will further test the prospects for achieving high-grade plasma confinement suitable to reactor operation.

Research with different types of pinched plasmas has made significant progress during the 1990s. The simplest in conception is the *z*-pinch (see the original article), where a current is directed in the *z* direction, producing a magnetic field that winds poloidally around this direction. This concept was one of the first for which the controlled-fusion problem was investigated in the 1950s. The conclusion was that the configuration is unstable. Nonetheless, in recent years there has been appreciable progress in the study of such pinches. When they are produced from thin fibers, extremely dense and hot plasmas are produced that are useful as x-ray sources and for understanding the interaction of plasmas with solids. By using many parallel strands of fiber, it is found that for short time intervals (of the order of microseconds) uniformity in the pinch is maintained. Because of the high densities and temperatures that have been achieved, proposals have now been made for demonstrating fusion power production with this concept.

Another pinch concept, the field-reversed pinch (FRC; see the original article) is also a candidate for demonstrating fusion power production. In the latter case, it is proposed to compress an FRC to high density and temperature using an imploding metal liner that produces magagauss magnetic fields. However, both types of pinch experiments are intrinsically pulsed, and it is now too premature to tackle the difficult problem of obtaining a duty cycle that would allow the consideration of commercial fusion power production.

The reversed-field pinch (RFP; see the original article) is a pinch more like a tokamak, in that it forms a toroidal plasma with toroidal and poloidal magnetic fields. In the 1990s, significant improvement of its parameters of operation and in the understanding of its physical mechanisms of turbulence have been made. This concept has also contributed to the understanding of the plasma dynamo problem of interest in astrophysics and to the understanding of how to control locked modes, which is crucial to understand in tokamaks as well as the RFP.

4.3 Final Statement

As a result of a great deal of progress, a plan for the demonstration of fusion-power production in a tokamak has been made. A detailed design for a fusion power-producing experiment has been completed, but cost considerations are likely to cause postponement of its implementation or a downscaled design. Many scientific issues remain to be clarified and other alternative paths are likely to develop. The physics issues that need to be resolved and the goal of a long-term energy source remain challenges to the technical creativity of mankind.

GLOSSARY

Alfvén Wave: A plasma wave that may be excited by alpha particles in a fusion plasma.

Burn: The self-sustained heating of a plasma arising from the fusion reaction.

Divertor: The edge region of a tokamak where field lines divert escaping plasma away from the immediate vicinity of the main discharge.

Energy Channeling: A proposed process to allow charged fusion products, with assistance from radio-frequency excitation, to heat ions rather than directly heating electrons.

Halo Current: Currents that are partially carried by the plasma but pass through the surrounding walls.

Ignition: The process whereby plasma heating transfers from being externally supplied to being internally supplied from the fusion reactions.

Magnetic-Field Ripple: The spatial modulation in the magnitude of the magnetic field due to the discrete number of toroidal field coils.

Pedestal: A region of plasma adjacent to the edge, where the plasma temperature abruptly rises.

Semidetached: A divertor plasma condition where a large fraction of the escaping plasma has recombined into neutral atoms.

Shear Flow: Flow of plasma that varies with minor radius.

Thermal Barrier: A region in a plasma where local transport properties are suppressed.

INTRODUCTION

With the advent of the Internet, communication systems are making an evolutional impact on people's lives all over the world. A large quantity of information in various categories, such as telephone, telegraph, computer data, and broadcast, and various services, including bi-directional moving pictures, are required to be transmitted through communication networks. Extremely high-capacity and flexible communication networks are required in order to serve these requirements. In these networks, pulse modulation schemes capable of transmitting a large quantity of data through a restricted communication band play an important role, as does the digital signal processing. This Addendum introduces modulators and demodulators widely used in up-to-date digital communication systems.

1. PULSE MODULATION METHODS FOR DATA-COMMUNICATION SYSTEMS

This section introduces advanced digital pulse modulation schemes and modulators and demodulators. Device and circuit technology are in common for various kinds of modulation schemes. The functions relating modulation and demodulation process, such as line filtering and timing extraction, represented in Sec. 1.2 are also used for other modulation schemes.

1.1 Advanced Modulation Method in Quadrature Phase-Shift Keying Scheme

Binary phase-shift keying (BPSK) and quadrature phase-shift keying (QPSK) modulation schemes have the highest performance and, therefore, are extensively used for various kinds of communication systems, such as sat-

ellite communication, mobile communication, and personal handy telephone systems. This section discusses modulators and demodulators for two types of advanced schemes based on QPSK:

1. offset quadrature phase-shift keying (OQPSK) modulation, which reduces signal distortion caused by nonlinear effects, and
2. quadrature quadrature phase-shift keying (Q^2PSK) modulation, which improves signal throughput.

1.1.1 Offset Quadrature Phase-Shift Keying Modulation (OQPSK). In the modulated signal using BPSK and QPSK schemes, there are abrupt phase transitions with maximum values of π at the boundaries of data. The large phase transition tends to increase signal distortion and to increase the outer band spectrum of the modulated signals when such signals pass through a relatively high-efficiency C-class power amplifier with saturation characteristics. There are several kinds of phase-shift keying modulation schemes to overcome the degradation by reducing the phase transition of the carrier at the data boundary. Offset quadrature phase-shift keying modulation (OQPSK) is the basic method among many kinds of modulation schemes with the small phase transition.

As shown in Fig. 1, the OPQSK modulator has about the same circuit structure as that for BPSK except that data in the quadrature channel are delayed by $T/2$, where T is the duration of the BPSK-modulated signal of in-phase and quadrature channels. Similarly, demodulation of OQPSK and MSK signals is done using a QPSK demodulator. In an OPQSK-modulated signal, the phase transition occurs in every $T/2$, but the signal spectrum does not increase because the operation is a simple summation. The sum signal at the phase transition point is produced by a vector sum of a continuous signal and a signal with $\pi/2$ (or $-\pi/2$) difference in phase at the transition point. Therefore, the maximum value of the phase transition reduces to $\pi/2$.

The degradation due to the phase transition at the boundary is minimized if we can realize a continuous phase condition at the data boundary. In the frequency-shift keying scheme, it is simply realized by selecting frequencies f_i to meet the orthogonal condition under which the total phase shift on each datum ($2\pi f_i T$) is equal to a multiple of 2π (this scheme is called CPFSK and extensively used). In the quadrature phase-shift keying scheme, it is realized by shaping each signal bit in both the in-phase channel (I channel) and the quadrature channel (Q channel) by weighting as shown in Fig. 1(c). The shaping is carried out by any of several weighting functions such as sinusoidal or Gaussian. The modulation scheme using a sinusoidal weighting function is called minimum-shift keying (MSK).

Reduction of the abrupt phase transition of OQPSK makes it possible to use the high-efficiency C-class power amplifier. This feature is effective for downsizing and light-weighting battery-assisted receivers.

1.1.2 Quadrature Quadrature Phase-Shift Keying Modulation (Q^2PSK). This modulation scheme is a focus of attention because of its effective utilization of the frequency resources and is now being applied in various communication systems. Figure 2 illustrates the structure of a Q^2PSK modulator. The scheme uses quadrature phase and an orthogonal shaping function as is used for the MSK. However, it encodes four bits per symbol, compared to two for conventional QPSK, and twice the data per modulation interval is accommodated. On account of the existence of an abrupt change of phase in the modulating signal as shown in waveform (*d*), this scheme requires an increase of 1.6 dB transmission power in order to provide an identical bit error rate for the same bandwidth. However, this scheme can obtain twice the throughput of QPSK.

A Q^2PSK modulated signal has both a phase transition and an amplitude variation in the overlap wave shape. In order to reduce the degradation due to nonlinear effects due to the power amplifier, a linearized saturation power amplifier, which has a saturation characteristic to the peak value without degradation on linearity against a wide range of input signal level, has been developed. Basically, this characteristic is attained by an A-class or AB-class amplifier whose gain is controlled according to the input signal level by some means, such as feed-forward technology, predistortion, and postdistortion. The linearized amplifier tends to be inefficient from the point of view of power consumption, but is now essential for a communication system having an abrupt

phase shift or a nonuniform amplitude envelope in its modulated signals. This technology is also applied on systems with modulation schemes presented in the following sections.

1.2 Digital Pulse Amplitude Modulation (PAM-DSB, PAM-SSB, and PAM-VSB)

This section introduces efficient digital modulation schemes for transmitting binary data through a restricted communication channel by using digital pulse amplitude modulation (PAM).

1.2.1 Modulator and Demodulator. Figure 3 illustrates a basic circuit configuration of a PAM modulator and demodulator. At the sending end, the input data sequence is subdivided and mapped onto a corresponding amplitude level of a multiple-level (M-ary) digital signal. The modulated signal is fed to the filter and transmitted through a baseband communication channel or modulated to form a bandpass data signal with a carrier using the conventional analog amplitude modulator: double sideband (DSB), single sideband (SSB), or vestigial sideband (VSB).

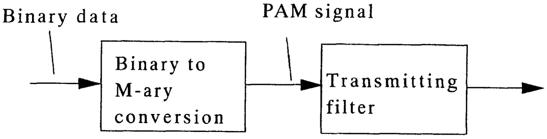
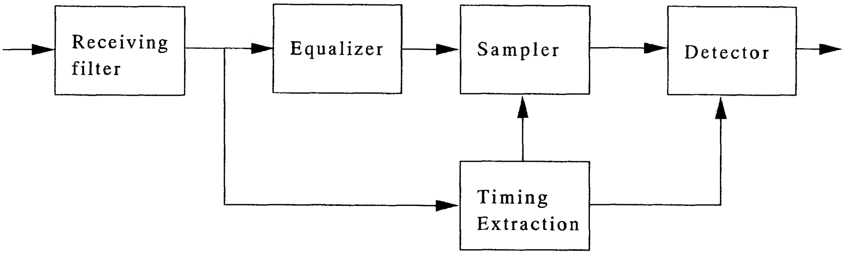
1.2.2 Timing Extraction. At the receiving end, the received signal must be sampled periodically at the symbol rate and the signal level must be detected by a decision circuit. We need a clock signal to perform the periodic sampling. One method for extracting the timing signal is for the transmitter to transmit simultaneously the clock frequency $1/T$ or a multiple of $1/T$ along with the information signal. The receiver may simply extract the clock signal by employing a narrow bandpass filter tuned to the transmitted clock frequency. This method has the advantage of being simple to implement but has several disadvantages, one of which is that the transmitter must allocate some of its available power and bandwidth to the transmission of the clock signal. There are a number of methods for extracting the clock from the received signal. Figure 4 shows typical circuits: In (a), the clock signal is detected directly using harmonics caused by nonlinear elements. In (b) the clock signal is generated by a VCO whose phase is controlled by the position of the input signal.

1.2.3 Equalization Process. The received signal is distorted by the communication channel by several factors, such as nonlinear amplitude and phase characteristics of the channel, or echo signal reflected at the discon-



(a)



(b)

FIG. 3. (a) PAM modulator, (b) PAM demodulator.

tinuity. This results in intersymbol interference at the output of the demodulator and leads to an increase in the probability of error at the detector. A channel equalizer is used for correcting or undoing the distortion. If the channel is precisely set and its characteristics do not change with time, we can design the equalizer easily. One example is a linear equalizer, which uses a finite–impulse-response filter or a transversal filter, as shown in Fig. 5. We often encounter channels whose characteristics are unknown or change with time. In these circumstances, the channel equalizer tracks the variations of the channel and adopts its coefficients to reduce the intersignal interference dynamically.

1.3 Quadrature Amplitude Modulation (QAM)

This modulation scheme is also called quadrature amplitude-shift keying. It has high efficiency and is extensively used in the modem in computer networks and various kinds of data communication systems including mobile radio, satellite communication, and the information superhighway. In this method, a single pulse in modulated signals contains multiple bits of information in the form of phase and amplitude. This scheme may be viewed as a form of combined digital amplitude and digital phase modulation.

The QAM signal employs two quadrature carriers, $\cos 2\pi f_c t$ and $\sin 2\pi f_c t$, each of which is modulated by an independent sequence of information bits to form a digital PAM signal. Adapting N-level PAM, we can transmit $M = N \times 4$ signal points with one PAM symbol. Therefore, the bandwidth required can be reduced to $1/(2 + \log_2 N)$ times that required for the ordinary BPSK system. A QAM system with up to 256 data points M is being used in an existing system.

1.3.1 Symbol Constellation and Mapping. In this scheme, information bits are mapped onto a two-dimensional complex signal space. Figure 6 illustrates examples of allocation of data points in signal space for an $M = 16$ QAM. These figures are called *symbol constellations*, and *mapping* is the procedure for assigning data symbols onto data points of the

FIG. 4. Timing extraction for PAM. (a) Spectral-line method. Since the received signal has no power spectrum at the clock frequency, it is fed to the nonlinear circuit to generate second-harmonic components of $1/T$ (Hz) and higher harmonics. The clock signal is extracted by a narrow-bandpass filter. (b) Early-late gate synchronizer. In this method, the input signal is correlated by two correlators with a reference signal over the symbol interval $1/T$; one of the correlators starts integration δT early relative to the estimated optimum sampling time and the other starts it δT late relative to the estimated optimum sampling time. The optimal sample point is found by adjusting the phase of the voltage-controlled oscillator that generates the estimated optimum timing of the reference signal so as to make the peak values of the two correlated wave forms coincide with each other.

constellation. These procedures strongly affect system performance.

On designing a constellation, one must consider the following factors:

1. The Euclidian distance between phasors (coordinates on the complex plane) should be minimized in order to realize the characteristic noise immunity of the scheme.
2. The minimum phase rotation between phasors, which determines phase jitter immunity, should be sufficient to stand up against clock recovery imperfection and channel phase rotation.

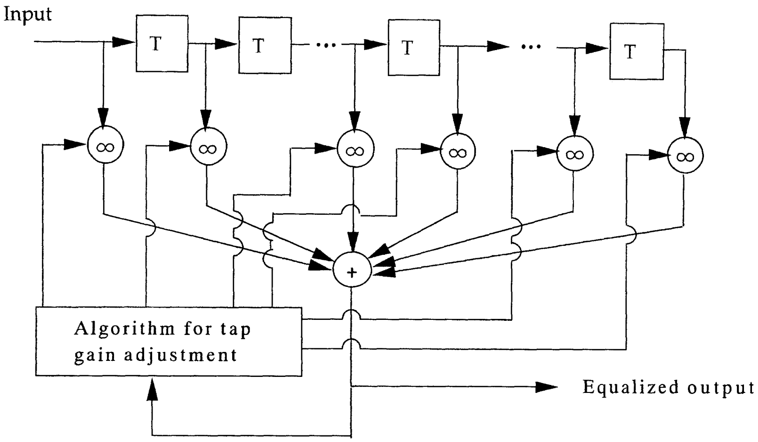

FIG. 5. Equalizer based on a transversal filter. In this circuit, tap coefficients are adjusted so as to realize the inverse frequency response of the channel.

3. The ratio of peak to average phasor power should be a minimum to ensure robustness against nonlinear distortion.

The rectangular constellation with Gray code mapping procedure as shown in Fig. 6(a) has merits with respect to power and signal-to-noise ratio. Systems using this scheme with the numbers of points up to 256 have been developed and are widely used as the standard modulation schemes for communication systems, such as modems. Figure 6(b) shows a circular (or star) constellation. This type of constellation does not have the equidistance condition between phasors. However, it has the advantage of being capable of employing a noncoherent demodulation process, which does not require complex carrier regeneration and AGC circuits. This scheme is extensively used for radio communication systems with a Layleigh fading channel, in which undesired multiple-echo signals with time-varying characteristics are superposed onto the desired receiving signal.

1.3.2 Modulator and Demodulator. Figure 7 shows a block diagram of a modulator and demodulator for a QAM signal with a rectangular constellation. In the modulator, the input data sequence is subdivided and mapped into two digital signal sequences whose amplitudes are modulated according to the input binary sequence, using the same circuit as that used for the PAM modulator. The two PAM signals produced are then modulated by sinusoidal carrier signals whose phases differ by $\pi/2$, using the same circuit as that used in a quadrature phase-shift keying (QPSK) modulator. In the demodulator, the received signal is divided into two PAM signals by multiplying the quadrature carriers in the same way as in the QPSK demodulation circuit. In the QAM demodulator, the same circuits or circuits based on the same principles as those of QAM and QPSK demodulators are employed to perform basic processes, such as synchronization and equalization.

In the circular constellation for 16-point QAM, the modulation process is performed through the encoding process shown in Fig. 8. The demodulation process is a differential decoding process of the modulated signal: The first signal is detected by comparing the signal amplitude at the data timing and that at the previous data timing. If there is a large change in amplitude then the first signal b1 is defined to be “1”, and otherwise “0”. This process is done by two adaptive threshold comparators. The remaining three signals are decoded by detecting the phase difference between the data and the previous data.

2. MODULATOR AND DEMODULATOR FOR SPREAD-SPECTRUM COMMUNICATION SYSTEMS

Spread-spectrum (SS) signals for digital communication were originally developed and

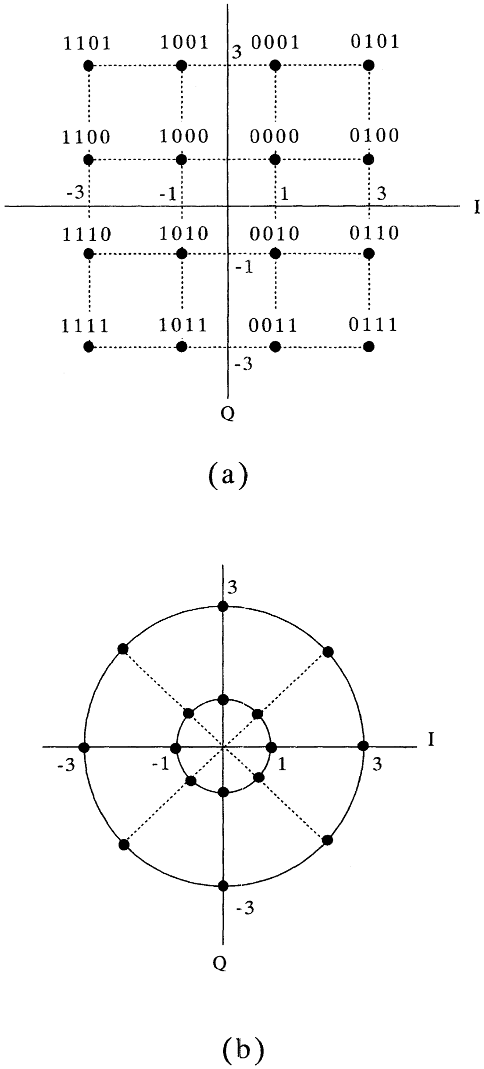

FIG. 6. Symbol constellation for QAM signal. (a) Rectangular constellation, so called from its shape in the signal space. This constellation has equidistant constellation points arranged in such a way that the average energy of the phasors is maximized. This scheme provides the higher signal-to-noise ratio to achieve the same bit error rate (BER). From the point of view of mapping, this example employ so-called Gray code mapping, in which the Hamming distance between a phasor and its closest neighbor is always 1. This procedure ensures that whenever a transmitted phasor is corrupted by noise that is incorrectly identified as a neighboring constellation point, the demodulator chooses a phasor with a single bit error. This minimizes the error probability. (b) Circular constellation. An example of the mapping procedure is illustrated in Fig. 8.

used for military communication to provide resistance to jamming, or to hide the signal by transmitting it at low power and thus making it difficult for the unintended listeners to detect its presence in noise. They are also useful for code-division multiple-access communications (CDMA) when two or more transmitters use the same common channel to transmit information, and they allow reliable communication through extremely noisy communication channels in which systems with conventional modulation schemes are useless. In addition to the robustness against interference, this modulation scheme has the excellent property of efficient usage of the limited bandwidth. Because of its features, this technology is expected to be useful for, and is now beginning to be applied for, a variety of civilian communication systems including satellite, mobile vehicle, and inter- and intra-office communication.

To overcome the problem of intentional or unintentional interference, the bandwidth of a transmitted signal is increased in this modulation scheme so that the bandwidth expansion factor W/R is much greater than unity (where W is the transmission bandwidth and R is the baseband data bandwidth). In addition, the information signal at the modulator is spread in bandwidth by means of a code (channel code) that is independent of the information sequence. The code has a pseudorandom property, so that it appears to be random to receivers other than the intended receiver, which uses the code to demodulate the signal. The usage of the channel codes allows great freedom in the choice of low interuser-interference codes. Proper choices of channel codes make it possible for a large number of users to communicate simultaneously through a limited bandwidth.

There are many kinds of modulation schemes in which the direct sequence scheme and the frequency-hopping scheme are generally used.

2.1 Direct-Sequence Spread-Spectrum Communication

A modulator for accomplishing the spreading in the direct-sequence (DS) scheme is shown in Fig. 9. Here, we assume that the binary information signal is at a rate $R\,(= 1/T_b$,

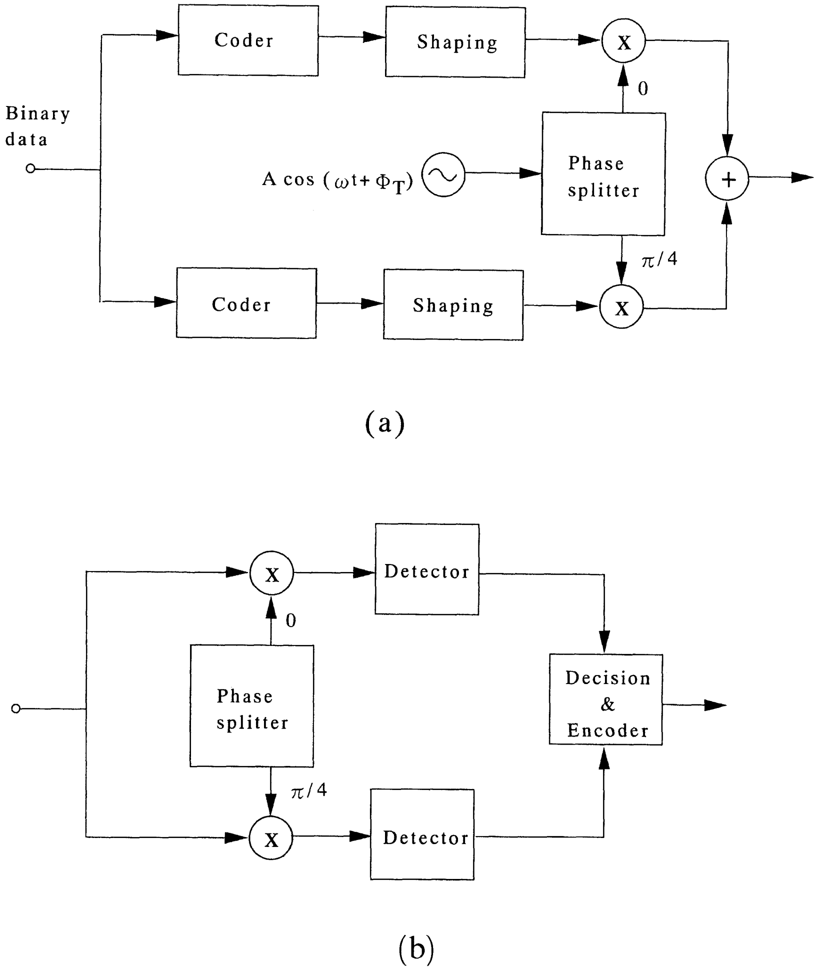

FIG. 7. (a) Modulator and (b) demodulator for QAM with rectangular constellation.

where T_b is the bit interval) bits per second and the available channel bandwidth is B_c Hz, where $B_c \gg R$. At the modulator, the information signal (a) is modulated with a bipolar type of pseudonoise [or pseudorandom noise, PN; this term is commonly used in this field as the same category of pseudorandom binary sequence (PRBS)] pulse sequence with its bit interval of $T_c(= 1/B_c)$ using the product modulator. The bandwidth of the information signal is expanded to $W = B_c$ Hz by shifting the phase of the carrier pseudorandomly at a rate of W times per second. The DC-SS signal is produced by modulating the expanded signal as shown in (c) with a sinusoidal carrier to form the BPSK signal and is transmitted through a communication channel.

We usually call a pulse in the PN code sequence the *chip*, T_c the *chip interval*, and $R_c = B_c$ the *chip rate*. The ratio of the bit interval to the chip interval $L_c = T_b/T_c$ is usually selected to be equal to the number of chips in the PN code sequence per information bit. The PN code sequence mentioned here is a code sequence of 1s and 0s whose autocorrelation has properties similar to those of white noise; the wave form of the autocorrelated signal has a steep peak at only one time point and at any other time position has a side lobe with a small noise amplitude. In the DS-SS

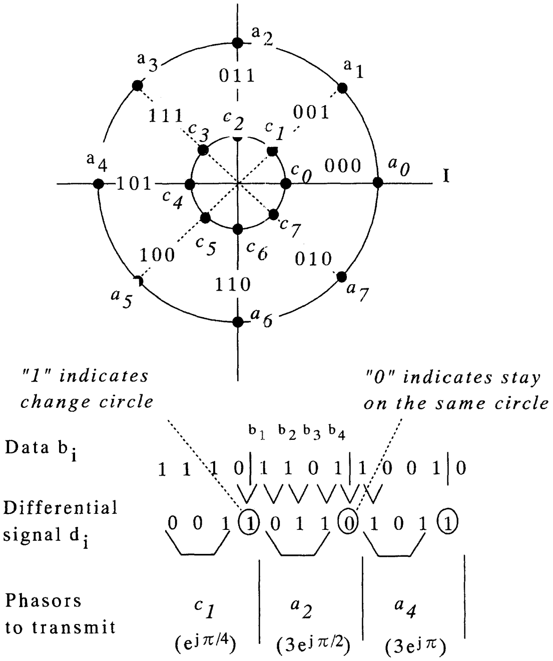

FIG. 8. Modulation process for 16-point QAM with a circular constellation. Of 4 bits in each symbol, b_1, b_2, b_3, and b_4, the first signal b_1 is differentially encoded onto the QAM phasor amplitude so that "1" causes a change to the amplitude circle that was not used in the previous signal and "0" causes the current symbol to be transmitted at the same amplitude. The remaining three signals are differentially Gray encoded on the circle with the same amplitude as that of the first signal.

system, the binary sequence with element $\{0, 1\}$ is mapped into a corresponding binary sequence with element $\{-1, 1\}$. The most widely known PN code sequence is the maximum-length sequence, which has a length $2^m - 1$ bits and is generated by an m-stage shift register as shown in Fig. 9(b).

The demodulation is the process of *despreading* of the spread signal. This is done by the circuits shown in Fig. 10. That in Fig. 10(a) uses direct cross correlation using a matched filter, such as a SAW correlator or convolver. This method has the advantage that demodulation can be performed with an extremely simple circuit and does not require a complicated synchronization process.

In the coherent demodulation process shown in Fig. 10(b), signal synchronization is critical to maintaining stable communication. The synchronization step can be separated into two distinct phases. The usual procedure for establishing initial synchronization is for the transmitter to send a known pseudorandom sequence to the receiver. The receiver is continuously in a search mode looking for this sequence to establish initial synchronization. In principle, matched filtering or cross correlation [as used in the circuit of Fig. 10(a)] are optimum methods for establishing initial synchronization in the presence of additive Gaussian noise. The matched filter establishes the initial synchronization in the same way as that of the modulator using a matched filter, and the demodulator enters the "data receive" mode. Examples of circuits for initial synchronization and tracking are shown in Fig. 11. Figure 11(a) shows an example of the initial synchronization method called a sliding correlator. The tracking is usually performed by means of a tracking loop called a delay-locked loop (DLL) as shown in Fig. 11(b). This implementation is equivalent to the early-late gate bit tracking synchronization described in Sec. 1.2.

2.2 Frequency Hopping

An example of the signal pattern of FH is shown in Fig. 12. In this scheme, the available channel bandwidth W is subdivided into a large number of nonoverlapping frequency slots. In any signaling interval the transmitted signal occupies one or more of the available

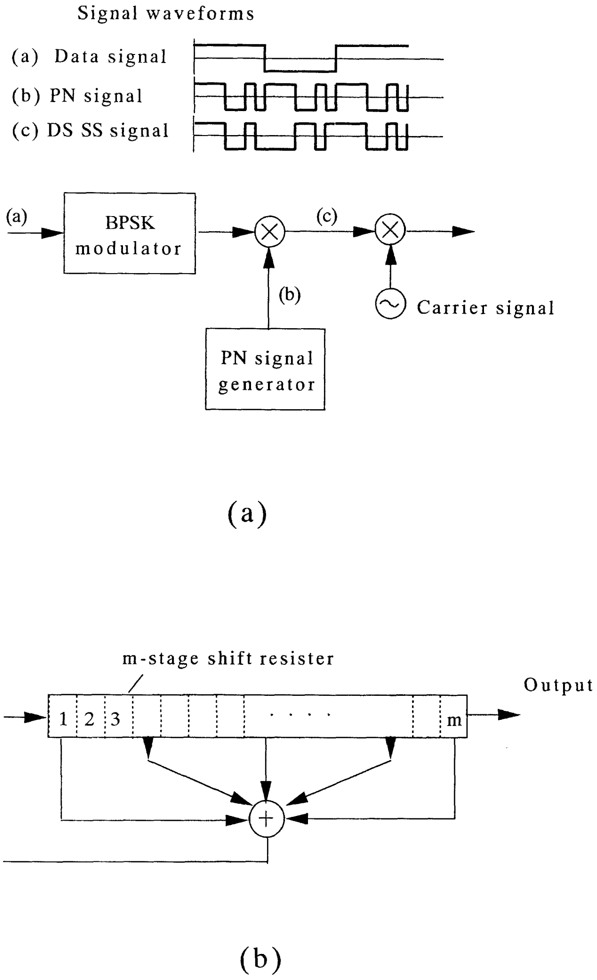

FIG. 9. Modulator for a direct sequence SS signal. (a) Block diagram, (b) maximum-sequence PN code generator.

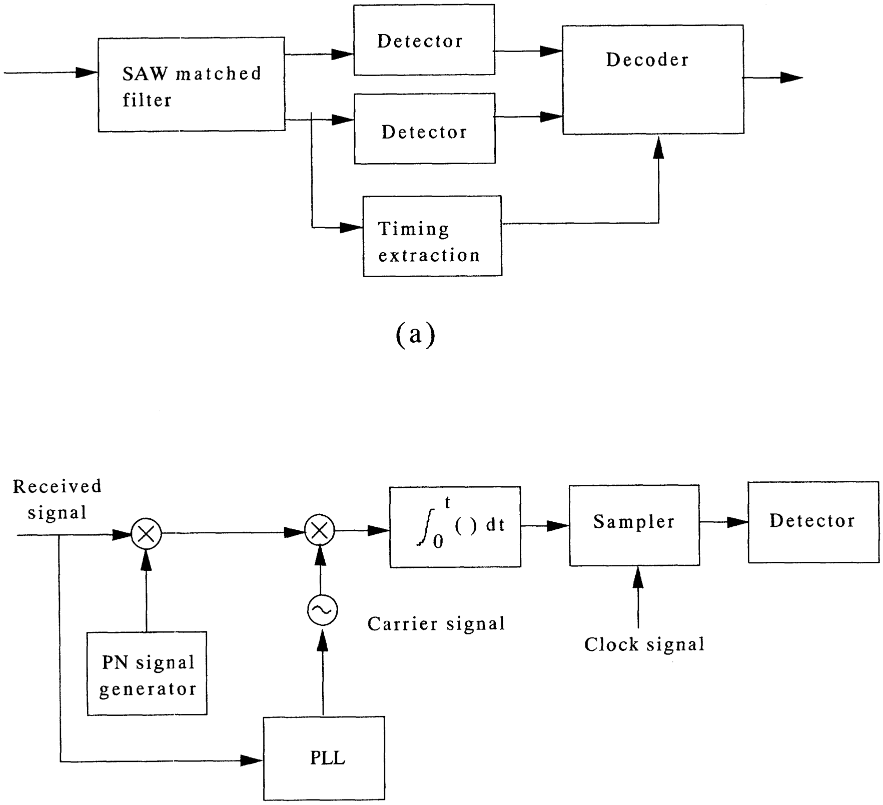
frequency slots. The selection of the frequency slot in each signal interval is made pseudorandomly according to the output from a PN generator.

A block diagram of the modulator and demodulator for a FH-SS system is shown in Fig. 13. The modulation is either binary or *M*-ary FSK (MFSK). For example, if binary FSK is used, the modulator selects one of two frequencies, say f_0 or f_1, corresponding to the transmission of a 0 or a 1. The resulting binary FSK is translated in frequency by an amount that is determined by the output sequence from the PN generator, which used to select the frequency f_c that is synthesized by the frequency synthesizer. This frequency is mixed with the output of the output FSK modulator and the resultant frequency-translated signal is transmitted over the channel. For example, by taking m bits from the PN generator, we may specify $2^m - 1$ possible carrier frequencies.

At the receiver, there is an identical PN sequence generator, synchronized with the received signal, which is used to control the output of the frequency synthesizer. Thus, the pseudorandom frequency translation introduced at the transmitter is removed at the demodulator by mixing the synthesizer output with the received signal. The resultant signal is then demodulated by means of an FSK demodulator.

A signal for maintaining synchronization of the PN sequence generator with the FH received signal is usually extracted from the re-



(b)

FIG. 10. Demodulator for a direct-sequence SS signal. (a) DS demodulation using SAW matched filter, (b) coherent demodulation. In (a), the received signal is autocorrelated by a matched filter and a compressed signal is generated directly by detecting the peak values from matched filters; thus the data will detected. In (b), the input signal is multiplied by the same PN sequence and is cross-correlated with a rectangular pulse of duration T_b. The data decision is performed by detecting whether the level of the output signal from the sampler exceeds thresholds.

ceived signal. Nonsynchronous detection is usually used for FH SS systems because it is difficult to maintain phase coherence both in the synthesis of the frequencies used in the hopping patterns and also in the propagation of the signal over the channel as the signal is hopped from one frequency to another over a wide bandwidth.

In the FH method, the initial acquisition process is to synchronize the known PN code sequence generated at the receiver that controls the hopping frequency pattern. The same procedures used in the DS signal synchronization procedure, such as serial search and sliding correlator, are useful for FH signals. However, it requires a long searching time. By employing multiple correlators in parallel, the searching time can be reduced at the expense of a more complex and costly implementation. For the tracking, the same technology as that used in DS-SS is applied.

3. OFFSET FREQUENCY-DIVISION MULTIPLEX

There exist some other modulation schemes with high efficiency in both transmission power and frequency resources. Among them,

FIG. 11. Methods for synchronization. (a) Sliding correlator for DS signal acquisition. The received signal is cross correlated with a rectangular pulse of $T_C/2$ seconds or less. Then integration is performed over the time interval NT_C, and the peak value of the output is compared with a threshold to determine if the known signal sequence is present. If the known threshold is not exceeded, the known reference signal is advanced by $T_C/2$ seconds and the correlation process is repeated. These operations are performed until a signal is detected or until the search has been performed over the uncertain interval. (b) Tracking using delay-locked loop (DLL). In this loop, the received signal is applied to two multipliers, where it is multiplied by two outputs from the local PN code generator, that are delayed relative to each other by an amount $2\delta < T_C$. The product signals are bandpassed and detected, and then subtracted. They are then applied to the loop filter that drives the clock VCO. The VCO output serves as the clock for the PN code-signal generator. In this process if the synchronization is not exact, the filtered outputs from two correlators will be different from each other and the phase of the VCO will be appropriately advanced or delayed. At the equilibrium point, the two filtered outputs will be equally displaced from the peak value, and the PN code output fed to the demodulator will be exactly synchronized to the received signal.

an excellent scheme is the offset frequency-division multiplex (OFDM) modulation. The operation principle of this system is that the original bandwidth is divided into a large number of narrow sub-bands in which the mobile channel can be considered to be non-

simply performed by a fast Fourier transformer (FFT) [or a discrete Fourier transformer (DFT)]. At the receiving end, the demodulation is also done by performing inverse discrete Fourier transform using an FFT. This scheme has the advantages of being implemented without a complex channel equalizer. Since the echo signal within a data interval contributes to an increase in the received signal power, this scheme has an advantage also in power efficiency, in addition to the robustness against multipath fading. Because of these features, this scheme is adopted for various digital wireless communication systems such as audio and digital TV broadcasting systems.

4. CONCLUSIONS

The basic concepts for modulation schemes stated here were proposed in relatively old days (several tens of years ago, or more). However, recent progress in device technology and global needs for communication systems as an infrastructure of social life accelerated the research and development of systems with these schemes. Technologies to improve system performances have also developed—for example, in DAM schemes, the development of linearized power amplifiers, adoption of error correction, and pilot-signal–assisted modulation—with the results that these systems are now in practical use in a wide area. As is represented by the information-superhighway concept, the importance of communication technologies is increasing still more, so that further development of technology of modulators and demodulators can be expected.

ABBREVIATIONS

DFT: Discrete Fourier transform.
FFT: Fast Fourier transform.
DLL: Delay-locked loop.
DS: Direct sequence.
DSB: Double sideband.
FH: Frequency hopping.
I-channel: In-phase channel.
Q-channel: Quadrature-phase channel.
MSK: Minimum-shift keying.
MFSK: M-ary frequency-shift keying.
OQPSK: Offset quadrature phase-shift keying.
PN: Pseudoranom noise.
PRBS: Pseudorandom binary sequence.
QAM: Quadrature amplitude modulation.
Q^2PSK: Quadrature quadrature phase-shift keying.
SAW: Surface acoustic wave.
SS: Spread spectrum.
SSB: Single sideband.
VCO: Voltage-controlled oscillator.

Deforming Nanocrystalline Metals: New Insights, New Puzzles

Jörg Weissmüller and Jürgen Markmann

1
Introduction

Grain boundaries are obstacles for motion, as evidenced by the increase of the yield stress of polycrystals with decreasing grain size embodied in Hall-Petch type equations. Thus, it is expected that when the grain size of a metal is reduced to extremely small values, as in nanocrystalline (nc) materials, dislocation activity should become comparatively less important in favor of alternative mechanisms which involve transport at grain boundaries, most notably diffusion creep and grain boundary sliding [1, 2]. One of the consequences of having a mechanism which circumvents bulk dislocation plasticity would be that materials which, in the coarse-grained state, are brittle due to a lack of active slip systems, might become ductile when in the nanocrystalline form.

The recent past has seen a revived interest in studies of the mechanical properties of nanocrystalline metals. Among the driving forces for this trend are the immense increase in performance of modern computers, which has enabled more and more realistic simulations of the deformation of these materials, leading to predictions on the underlying microscopic processes which have stimulated new experiments. The synergy between experiment and simulation is critically assessed in the comprehensive review, Ref. 3 Equally important has been the advent of materials of improved quality. Notably, ultrafine-grained materials [4] (with grain size D of roughly 100–500 nm) can be produced in considerable quantity, and nanocrystalline sheets with D of the order of 50 nm can be obtained by electrodeposition. At the lower extreme of the size scale are materials produced by assembling inert-gas condensed clusters in situ to form bulk materials; grain sizes down to 5 nm can be obtained by this technique. As compared to early studies, from which the first suggestions for modified deformation mechanism and modified stress-strain relations at nanometer grain size emerged fifteen years ago [1, 2], we now have at hand samples of considerably reduced porosity and enhanced purity. As an example, Figure 1 displays an inert-gas condensed (igc) nanocrystalline Pd sample.

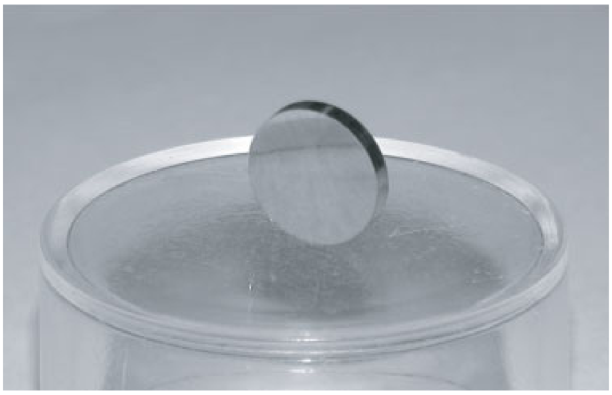

Fig. 1 Bulk nanocrystalline metal samples with grain sizes down to about 10 nm can be produced by in-situ consolidation of inert-gas condensed nanoparticles in an UHV environment. The Pd sample in the image has the diameter 8 mm and thickness of about 0.5 mm. The initial density, typically 91–93% of bulk Pd, is increased to 96–97% after deformation by rolling.

Previous studies of the deformation of igc materials, using micro tensile tests, found brittle behavior or strain to failure of not more than few percent [5]. By contrast, more recent studies showed that high density, high purity igc samples can be deformed to a true strain in excess of 0.5 by rolling. For the first time, this has now made it possible to study systematically the evolution of the defect structure and of the microstructure during the deformation of truly nanocrystalline bulk metals [6, 7]. Here, we highlight some of the issues which have arisen from these experimental studies.

2
Diffusion Creep

It has been suggested early-on that the rate of Coble creep, which is based on transport via grain boundary diffusion and which varies as D^{-3}, could become the dominant deformation mechanism at small grain size, even at room temperature. Recent studies of the deformation of nc Pd at small stress find the creep rate quantitatively compatible with the estimated rate of Coble creep [6]. There is a considerable uncertainty in such measurements, *i*) due to the extrapolation of the grain boundary diffusion coefficients – which were measured at high temperature – to room temperature, and *ii*) because no steady state creep was established. Still, the findings can be discussed with respect to the proposition of dominantly diffusive deformation: Markmann et al. measured strain rates of 10^{-10}/s at the stress of 10 MPa [6]. Since the stress for diffusive creep varies linearly with the strain rate, this means that an unphysically high stress, of the order of 10^{10} MPa, would be required to achieve the strain rates of the order of 10^{-1}/s required in industrial forming processes. Even when a large margin of error is admitted, this would seem to rule out Coble creep as a practicable deformation pathway at room temperature.

It is an open question how this finding can be reconciled with the observation that nanocrystalline metals, if their grain size is not stabilized – intentionally by alloying or unintentionally by voids or impurities – undergo significant grain growth even at room temperature [8]. This testifies to an extraordinarily high atomic mobility in the grain boundary cores. When the grain size doubles, typically within a few days for Pd at $D = 8\,\text{nm}$ and $T = 300\,\text{K}$, the number of grains has been reduced by the factor of eight, so at least 7/8 of the atoms have been displaced from their original lattice site. Since grain growth does not intrinsically entail a plastic deformation, it is conceivable that grain boundary migration simply does not couple to the stress and so does not contribute to the creep rate.

3
Grain Boundary Sliding and Grain Rotation

It is well established that grain boundary sliding plays an important role in the superplastic deformation of conventional coarse grained materials. Since the number of grain boundaries per volume increases as the grain size is reduced, it can be expected that sliding is a relatively more important process at smaller grain size. Intricately linked to this issue is that of grain rotation. Dislocation glide on preferred slip systems gives rise to rotation and to crystallographic texture. By contrast, grain rotation via grain boundary sliding along may randomize the grain orientation distribution. It is therefore remarkable that experiments on nc Pd deformed to a large true strain, 0.6, by rolling at room temperature show that the random grain orientation distribution of the starting material is maintained, whereas coarse grained Pd deformed under identical conditions develops a pronounced rolling texture [6]. This provides strong evidence for a significant role of grain rotation in the deformation of the nanocrystalline metal, similar to the grain rotation during superplastic deformation of coarse grained materials at elevated temperature. In fact, individual rotation events (apparently coupled, in the experiment, with grain growth) have recently been observed by in-situ transmission electron microscopy (TEM) [9].

Grain boundary sliding over finite distances requires changes in the grain shape. Therefore, an accommodation process must be active in parallel. Hahn and Padmanabhan [10] have proposed a mechanism that circumvents accommodation when the grain size of nanocrystalline ceramics becomes comparable to the grain boundary thickness. For metals, where the grain boundary thickness is of the order of one interplanar spacing [11], the required extremely small grain sizes have not been reached so far. However, the formation of mesoscopic shear planes – stretches of several coplanar grain boundaries in a row which facilitate fast deformation via sliding with little accommodation – during the superplastic deformation of metals with grain sizes in the micrometer-region is well supported by experiments [12]. These features have also been observed in nanocrystalline materials, both by computer simulation [13] and by experiment [6]. However, more systematic investigations are required to determine how frequent these features occur and how significantly they contribute to the deformation. Most observations of nanomaterials so far show serrated grain boundary networks between polygonal grains, in which sliding can only be understood if it is accompanied by accommodation. With diffusive transport ruled out, dislocation plasticity is the obvious candidate for the accommodation process.

4
Dislocation-Mediated Plasticity

4.1
Are Nanomaterials Dislocation-Free?

Isolated nanocrystals are often free of dislocations, which would be attracted to the surface by large image forces. By analogy, one may assume that undeformed nanocrystalline materials are free of dislocations as well. Experiment does not support this view: dislocations have been repeatedly observed, even in the immediate vicinity of grain boundaries

[7]. This is not too surprising when one considers the fact that grain boundaries can transmit both normal and shear components of the stress to the neighboring grains, so that the magnitude and even the sign of the image forces are less obvious than at free surfaces. Furthermore, microstrain is ubiquitous, and has even been proposed to be intrinsic to the small grain size [14]. The local strain may balance image forces, stabilizing dislocations in the interior of nanograins.

It is worth mentioning that a typical RMS microstrain value in nanocrystalline fcc metals is $\langle \mu^2 \rangle^{1/2} = 0.005$ at the grain size $D = 10\,\mathrm{nm}$; [14] for Pd this translates into an RMS stress of roughly 0.6 GPa, of the same order as typical yield stresses of nanocrystalline metals [5, 15]. This large variation in local stress values complicates the analysis of experiments in terms of microscopic mechanisms relying on a well-defined stress state.

4.2
Do Dislocations Contribute to the Plasticity?

At room temperature and not too small strain rates, conventional coarse grained metals deform by dislocation glide. The Frank-Read source provides a conceptual frame for the yield stress as well as a mechanism for dislocation multiplication. As the deformation proceeds, the dislocation density increases and the interaction between dislocations on different slips systems in coarse-grained materials leads to work hardening. Even at this most simple level of understanding, it is subject to doubt if the conventional concepts of dislocation plasticity apply to nanomaterials.

In spite of the observation of dislocations in nanograins, there is so far no reported observation of a Frank-Read source in a nanocrystalline solid. Once again this is not surprising, since the stresses involved would be prohibitive: by inspection of Figure 2 it is readily seen that the largest possible source would require a distance between pinning points of $L > D/3$. The Orowan stress is at least (in the case of a pinned edge dislocation) $\lambda = Gb/L$. For a full dislocation and a Shockley partial in Pd this evaluates to 2.4 GPa and 4.8 GPa at $D = 10\,\mathrm{nm}$, respectively, when $L = D/4$ is used. These stresses are above the highest yield stress reported so far for nanocrystalline pure metals.

In spite of the fact that the high critical stress makes the action of standard dislocation sources unlikely, experiments have recently confirmed that dislocations are active during the deformation of nanocrystalline fcc metals. By HRTEM, Chen et al. [16] found twins in deformed thin films of nc Al. Rösner and coworkers confirmed the existence of twins by investigation of deformed nc Pd [7]. Markmann et al. investigated bulk nc Pd deformed by rolling; by means of x-ray powder diffraction they found that a large density of stacking faults develops as the deformation proceeds [6]. Stacking faults have also been found in HRTEM work on deformed nc Al [17]. Faults and twins are created by the motion of partial dislocations, they are therefore indicative of deformation via the glide of lattice dislocations. Thus, there is now compelling experimental evidence of dislocation activity contributing to the deformation of bulk nanocrystalline materials.

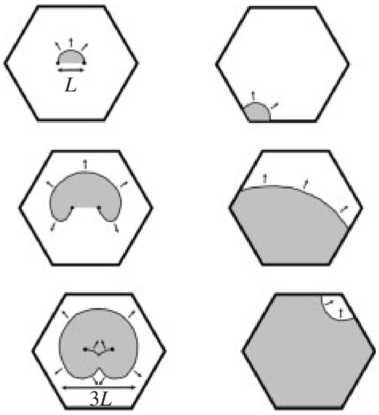

Fig. 2 Dislocation multiplication by activation of a Frank-Read source with distance L between pinning points in a conventional coarse-grained metal (left) and dislocation nucleation and adsorption in a nanograin (right). The hexagons represent the respective grains, and the shaded area represents the sheared region of the slip plane.

4.3
Dislocation Nucleation versus Multiplication

Molecular dynamics simulations explore the regime of very high stress, since high strain rates are imposed by the short computational timescale. Still, even at these high stresses no observation of dislocation emission from Frank-Read sources has been reported. Instead the simulations indicate that a fundamentally different mechanism is active [18, 19]: New dislocations, often partials, nucleate at grain boundaries, transverse the grain, and are then absorbed by the grain boundary on the opposite side of the grain, as sketched in Figure 2. Thus, the dislocation density does not increase as the deformation progresses. In agreement with this notion, nanocrystalline fcc metals exhibit unusually low work hardening [15, 20].

If one was to accept this mechanism of dislocations popping into a grain at grain boundaries, and popping back out at the opposing boundary as the elementary event of dislocation plasticity at small grain size, a number of emerging fundamental issues would require to be addressed:

i. What is the microscopic mechanism of dislocation nucleation at grain boundaries?
ii. Which type of dislocation will be emitted?
iii. What is the required (local?) stress?
iv. How is the local strain concentration at boundaries, associated with the nucleation and absorption accommodated?
v. Is there an energy barrier for nucleation, and what is the role of thermal activation in overcoming it?

So far, few arguments endowed with predictive power have been brought forward in this field. A possible exception will be critically discussed in the next section.

4.4
Faulting versus Twinning

Chen et al. [16] have made a suggestion on question *ii.* of the previous section: by analyzing the dislocation emission from a Frank-Read source they showed that, when the anchor spacing becomes very narrow, the emission of partials is favored over that of full dislocations. They argued that this explains why nc Al forms twins upon deformation, in spite of the materials high stacking fault energy. The observation of twinning in Pd [7], another high stacking fault metal, supports these findings.

The argument by Chen et al. exploits the fact that the area of the fault decreases faster, with diminishing dimension, than the line-length of the dislocation. Thus, at small size the low energy partial dislocation is preferred over the full dislocation, in spite of the extra energy stored in the faulted area of the glide plane. These considerations are convincing, but their combination with the Frank-Read source entails the complications addressed above: no experimental confirmation, unrealistically high activation stress. In fact, Rösner et al. [7] have reported an observation which is not readily explained in terms of the Chen model or of a recent refinement [21]: in Pd deformed by rolling at strain rates near $0.08\,\mathrm{s}^{-1}$ they found abundant faulting, but no twinning. By contrast, when the strain rate was raised to $0.3\,\mathrm{s}^{-1}$, abundant twinning was observed. In other words, the mere fact that partial dislocations can be generated does not automatically imply twinning. Instead, there appears to be a barrier to twinning which is only overcome at the higher strain rate. The nature of this barrier is not understood so far.

It is generally acknowledged that deformation twinning results form the cooperative passage of partial dislocations on successive glide planes. The details of this process are the subject of debate even for conventional materials, and it is not obvious in how far concepts such as the pole mechanism or double cross-slip are transferable to situations where – as it appears to be the case in nanomaterials – each individual partial dislocation has to nucleate separately from a high-angle grain boundary. Even more puzzling is the formation of arrays of very finely spaced twin lamella, where the process acquires an extra characteristic length-scale of periodicity, the lamellae spacing [7].

4.5
Slip System Selection and Alignment by Grain Rotation

A significant observation is that, within each individual grain, all deformation twin boundaries are coplanar, as is shown in the high resolution TEM image of Figure 3. Apparently, the twin networks – involving twin boundaries on more than one crystallographic set of planes – which were found in MD simulations [22] require the vastly higher strain rate (of the order of $10^7\,\mathrm{s}^{-1}$) of the numerical studies, and the associated high stresses. This indicates that large stresses would be required for transmitting dislocations through twin boundaries. An interesting consequence is that exceptionally high yield stresses and significant strain hardening can be reached with samples of micrometer grain size and nanoscale twin spacing, as was recently demonstrated for Cu [23]. Remarkably, however, similar strain hardening has not so far been reported for truly nanocrystalline samples in spite of the tendency to form deformation twins, nor are the products of dislocation-twin interactions observed. This indicates that an

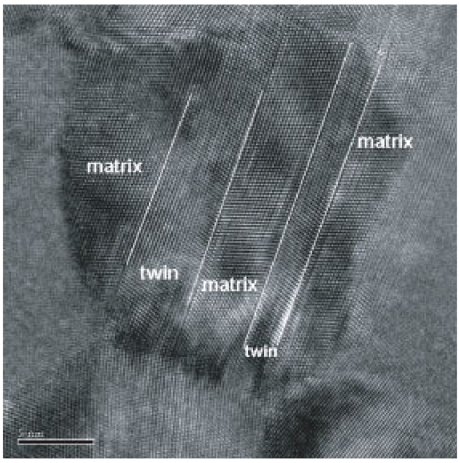

Fig. 3 High-resolution transmission electron micrograph of nc Pd deformed to a true strain of 0.32 by rolling at the strain rate μ = 0.3/s. After Ref. [7].

alternative deformation pathway may be active in nanocrystalline materials, which avoids the activation of slip systems that intersect the deformation twin boundaries.

Rösner et al. [7] have highlighted this issue from a different angle. They pointed out that the finding that twinning selects exclusively parallel planes in deformed nc Pd raises a puzzling question: it implies that only one glide system is active within each grain, significantly short of the five independent glide systems that are required for a general deformation in a polycrystal (after von Mises). In view of the large true strain value in their experiment, and of the presence of grain rotation (see above), it appears likely that the local direction of principal shear stress experienced by any given grain varied as the deformation proceeded. As the material apparently did not activate a second slip system once it had decided on the direction of twinning in the early stages of deformation, other processes than dislocation glide must then have become active for further deformation to be possible.

Rösner et al. suggested that grain rotation may provide the requested degree of freedom: it allows each nanograin to adjust its orientation in such a way that, throughout all stages of the deformation, the active glide plane remains aligned in parallel with the local shear direction. If this behaviour, which is sketched in Figure 4, could be confirmed in materials other than fcc metals, it could provide a – highly desirable – mechanism for achieving plasticity even in materials with less than five active slip systems if the grain size is small enough.

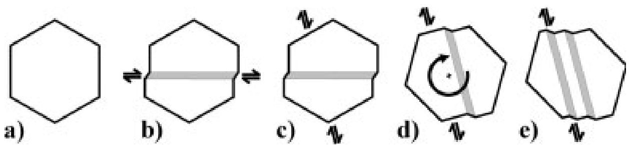

Fig. 4 Twinning and slip system alignment by rotation as suggested in Ref. [7]. The undeformed nanograin (a) is sheared along the slip system with maximum projected shear stress λ_{max} (arrows) by twinning (b), thereby selecting the single active slip system. At a later stage of deformation, the local direction of λ_{max} has changed (c). Since the deformation along the corresponding slip systems is blocked, grain rotation (d) is required to align the active slip system with λ_{max}, leading to further deformation (e).

5
Deformation Mechanism Maps

The recent experimental and simulation results on the deformation of nanocrystalline fcc metals have arguably raised as many questions as they have provided answers. Yet, the field has clearly moved beyond the early stage where the question 'what is the active deformation mechanism in nanocrystalline metals' summarized the direction of research. The body of available results indicates that there is not 'the' deformation mechanism. Instead, depending on the grain size, temperature, and stress or strain rate quite different mechanisms may be dominant. Quite analogously to conventional materials one may therefore attempt to summarise the insights on microscopic processes in the form of deformation mechanism maps for nanocrystalline materials.

Deformation maps can be drawn in various representations. We find it useful to plot the mechanism in the plane spanned by the grain size as the abscissa and the strain rate as the ordinate. A tentative map plotted in this way is shown in Figure 5. As discussed above, the map shows Coble creep at very small strain rate, followed by the combination of partial dislocation activity with grain rotation and grain boundary sliding as discussed above, including the transition from faulting to twinning. At the highest strain rate, the map lists the formation of twin networks as indicated by MD simulation [22]. Also a results of MD work is the transition to a dominantly sliding-controlled deformation at the very

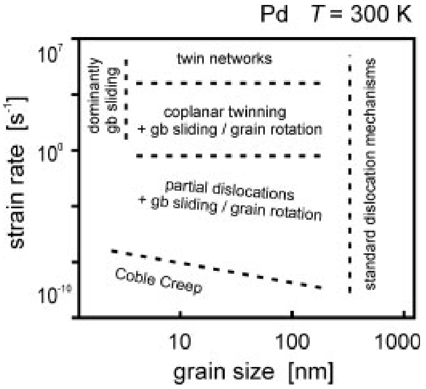

Fig. 5 Tentative deformation mechanism map for Pd at small grain size. See text for details.

smallest grain size and high strain rate [24], represented by the top left region of the map. It is emphasized that the regime of strain rates covered by the combined experimental and simulation studies extends over 17 orders of magnitude; in view of the few available results it appears highly likely that processes not so far identified are active in regions of the deformation map which have not yet been explored. Therefore, a representation such as Figure 5 cannot aspire to represent a complete picture of deformation mechanisms in nanomaterials; it should be viewed as an attempt to provide a snapshot of the available knowledge in a field which is evolving quickly.

As a further word of caution we emphasize that the map of Figure 5 combines data collected in the different stress states associated with uniaxial tension (MD simulations and creep) as compared to rolling. The hydrostatic stress component, compressive in rolling versus tensile in uniaxial tension, may affect the dislocation processes via their activation volumes. On the other hand, in view of the highly nonuniform local state of stress of a polycrystalline material during deformation, and in view of the very high stresses of both signs associated with the microstrain in nanocrystalline materials, attempts at rationalizing their behaviour in terms of processes related to a well-defined state of stress, with a uniform hydrostatic stress component, may not necessarily succeed in capturing the full phenomenology. Thus, in a qualitative way, the map of Figure 5 may still provide a useful picture of what is going on.

The entries in the map referring to MD simulation results highlight one of the mayor obstacles in comparing the simulation results to experiments: while the system sizes in MD simulation have been increasing over the years, to the extent where constraints on the size may have little effect on the predictions for atomic-scale processes, the time-scales remain exceedingly short, and strain rates many orders of magnitude faster than those in standard experiments as well as in industrial forming processes are required for significant deformation to occur within the time of the simulation. Inasmuch as the dominant deformation mechanism is strain-rate dependent, caution is required when concluding on realworld behaviour based on simulation data. This statement does nothing, of course, to diminish the extreme usefulness of MD simulations in stimulating both targeted experimental studies and new theoretical approaches for analysing and understanding the microscopic processes underlying the deformation of nanocrystalline materials. With the advent of improved samples and more systematic studies of deformation, the experimental data base on which this understanding rests is rapidly expanding.

Nanotechnological Aspects in Materials for Hydrogen Storage

Maximilian Fichtner

Introduction

Hydrogen storage is regarded as one of the key issues which have to be solved in the developing field of hydrogen technology [1, 2]. Of the various ways of storing hydrogen for fuel cell-driven applications, however, conventional storage systems based on liquefied and pressurized hydrogen exhibit principal drawbacks.

Pressurized hydrogen can be stored in containers made of composite materials that have to withstand pressures of up to 700 bar in order to carry enough fuel for a reasonable driving cycle of 400–500 km. In this case, however, there are safety concerns related to a tank rupture in an accident. Technical problems arise e.g. from adiabatic effects when expanding and compressing the hydrogen during refuelling. Furthermore, current containers do not allow operation at temperatures below freezing point due to the risk of failure of the composite structure.

To increase the stored mass per container volume, liquefied hydrogen with a density of 70.8 kg/m^3 is particularly attractive. For this purpose, the hydrogen has to be cooled down to 21 K, which, however, needs about one third of the energy content of the stored hydrogen. Overall efficiency is further reduced by a finite heat transfer through the insulated vessel, leading to a loss of 2–3% of vaporized hydrogen per day. In order to prevent a high pressure build-up (the critical temperature of hydrogen is 32 K), the overpressure must be released from the tank, e.g. via a catalytic converter.

A practical solution to circumvent these drawbacks would be storage in a material that can readily take up and release large amounts of hydrogen. According to car manufacturers and the technical targets of the US Department of Energy for 2010 and 2015, more than 6 wt.% of hydrogen should be contained in such a system, including tank and valves, and the filling time should not exceed 5 min. Furthermore, the thermal properties of the material have to match the operation conditions of the fuel cell, which means that the temperature necessary to release the hydrogen from the storage should not exceed the temperature of the exhaust gas of the fuel cell.

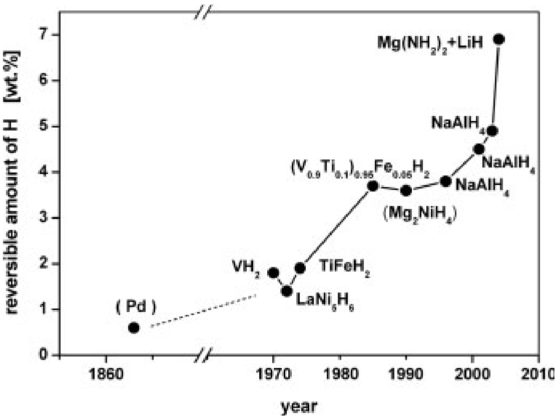

Fig. 1 Development of the gravimetric storage capacity of low- and medium-temperature hydride systems.

Development of such a material is a challenge and up to now no system has been found that would be able to fulfil all requirements. Although considerable progress has been made concerning the storage capacity in the last 30 years (see Fig. 1), the advancements resulting from the investigation of single compounds have not yet led to a solution. Hence, new concepts as well as a multidisciplinary approach are being pursued in order to both increase the reversible storage capacity and the kinetics of hydrogen exchange of systems with suitable thermodynamic properties.

Recent investigations (e.g. [3–6]) have shown that nanoscale materials may offer advantages if certain physical and chemical effects related to the nanoscale can be used efficiently. Associated phenomena, such as surface interactions, material transport, defects, vacancies, phase transitions, grain boundary phenomena, and the formation of new and metastable phases may also play an important role in the development of reversibly working hydrogen storage materials with a high cycling stability.

In practice, two basic mechanisms may be considered for hydrogen storage in nanoscale materials:

- **Physisorption** of molecular hydrogen in a nanomaterial.
- **Chemisorption**, including dissociation of hydrogen molecules and chemical bonding of the hydrogen atoms by integration in the lattice of a metal, an alloy, or by formation of a new chemical compound.

Each principle has its own prospects and constraints. Chemisorption materials may provide high volumetric and gravimetric storage capacities, but there is always the need to split or recombine the hydrogen molecule and chemically bond or release the atoms while forming the compounds. This is a process that inherently involves big enthalpies which have to be handled in a technical application.

Storing hydrogen by physisorption is not subject to this constraint, because the hydrogen stays in its molecular form. The problem rather is to provide light materials with a sufficient amount of bonding sites for the hydrogen per volume. Moreover, physisorption interaction between the H_2 molecule and the surface is in the lower kJ/mol range, as a result of which it may be necessary to go to very low working temperatures.

The present article shall give an overview of the current state of the art of nanomaterials developed for hydrogen storage on the basis of these principles. Material-relevant nanotechnological aspects of preparation and properties shall be outlined and strategies shall be presented for the further development of the materials.

1
Hydrogen Storage by Physisorption

Physisorption is a principle where the forces involved are weak intermolecular forces (van der Waals forces) which do not cause any significant change in the electronic orbital patterns of the relevant species. The challenge associated with the physisorption of hydrogen results from the fact that H_2 is the smallest molecule and only has two electrons. Hence, it is hard to polarize, and dispersion forces created by temporarily induced dipoles are comparably weak.

Despite these peculiarities, nanomaterials may offer advantages for molecular hydrogen storage when they exhibit high specific surface areas and when the chemical and spatial environment of the hydrogen can be designed on a molecular level.

An alternative for storing hydrogen by physisorption on large surfaces is hydrogen storage by encapsulation or trapping in microporous media. The working principle is that the guest molecules are forced into the cavities of the nanostructured host. Upon cooling, hydrogen is trapped inside the cavities. It can be released again by raising the temperature. Thus, trapping may be an instrument to overcome the low binding energies between the molecular hydrogen and the support.

For bonding hydrogen molecules in nanostructures, several approaches have been pursued:

1. Physisorption in materials with large surface areas.
2. Trapping in stable nanostructures.
3. Trapping in temporary nanostructures.

Of the currently investigated physisorption materials, nanostructured carbons, zeolites, metal-organic frameworks, and clathrates shall be discussed below.

1.1
Nanostructured Carbon

Nanostructured carbon materials, such as graphitic nanofibers (GNF), multiwalled carbon nanotubes (MWNT), single-walled carbon nanotubes (SWNT), and carbon nanohorns, exhibit novel properties and yield unusual scientific phenomena, as was shown in a number of studies. The chemistry of the non-planar carbon structures differs from that of the planar graphite, because the non-planar backbone reduces the orbital overlap of the π electrons. This causes localization of the double bonds, which affects the overall chemistry.

A particular interaction of hydrogen molecules with carbon nanomaterials was expected to be possible and in 1998, a storage capacity of 67 wt.% H was reported for graphitic nanofibers [9]. Since then, a number of experimental studies have been conducted, but such high values have not yet been reproduced by other groups. Moreover, the hypothesis of unusually high storage capacities was not supported by theoreticians. According to Wang [8], no graphite-hydrogen potential can account for the values reported.

At the same time, first publications reporting high storage capacities in carbon nanotubes resulted in extensive research activities yielding many experimental data and a similar, still ongoing controversy [10]. Figure 2 gives an overview of data published in this field. Nijkamp et al. [14] and Zuettel et al. [15] found that the amount of adsorbed hydrogen was proportional to the specific surface area (BET) of the carbon material and limited to 2 wt.% hydrogen at 1 bar H_2 and 77 K. Recent studies of hydrogen uptake at 77 K in various carbon nanostructures indicated that the storage capacity depends on the surface area only and not on the long-range

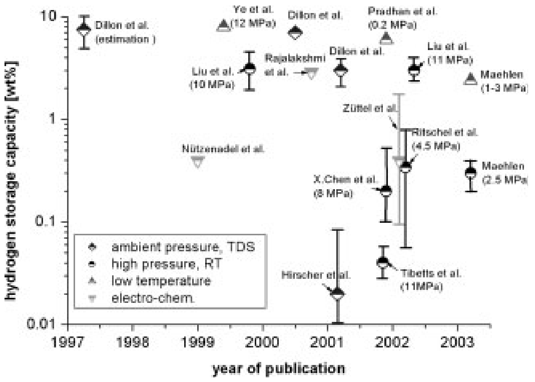

Fig. 2 Experimental data regarding hydrogen storage capacities in SWNTs versus publication year for different methods, pressures, and temperature regimes [11].

order or curvature of the graphene sheets [16]. When cathodically charging GNF, SWNT, and MWNT with hydrogen under ambient conditions, the reversible hydrogen uptake was 1.5 wt.% H per 1000 m^2/g [15].

Several attempts were made to modify carbon materials with the aim of producing designated binding sites for molecular hydrogen at introduced defects and stacking faults. Orimo et al. [12] showed that nanostructured graphite can be made to hold up to 7.4 wt.% hydrogen if the graphite is prepared by 80 h reactive ball milling under a 1.0 MPa hydrogen atmosphere. However, hydrogen desorption starts at about 600 K with maxima around 800 K and 1050K [17, 18]. Hirscher et al. [13, 18] concluded that the uptake of hydrogen was mainly due to the formation of covalent C-H bonds during ball milling rather than to bonding by physisorption at designated binding sites.

Use of a supported catalyst as a hydrogen source may considerably enhance the overall hydrogen uptake of a carbon material, as was reported by Lueking and Yang [7]. In this work, 1–3 $cm^3 H_2/g$ (STP) were adsorbed on various undoped carbon materials (SWNT, MWNT, GNF, and activated carbon) at 300 K and 0.1 MPa H_2. Mixing of carbon nanotubes with palladium nanoparticles (dispersion ~50%) increased the uptake of the carbons by a factor of three. This effect was explained by hydrogen spillover from the catalyst particles to carbon receptors at the surface of the nanotubes. However, baseline carbon adsorption was below 0.1 wt.% and the predominant factor in the magnitude of the overall hydrogen uptake.

A new type of nanoporous carbon with a controlled microporous or mesoporous structure, the so-called carbide-derived carbons (CDCs), was presented recently [105]. The material is produced by a high temperature process from carbides (e.g. SiC or Ti_3SiC_2), by removing metals and metalloids as volatile chlorides, leaving a noncrystalline carbon with up to 80% open pore volume. A regular porous structure is obtained with a narrow pore size distribution depending on the type of carbide and the conditions of chlorination. The specific surface area is up to 2000 m^2/g, the pore size distribution is narrow (0.5–1.5 nm), the pore volume is up to 1 cm^3/g of the material. Up to 3 wt.% hydrogen can be adsorbed at 77 K and 1 bar H_2 pressure. It was concluded in [105] that a uniform and open porosity with pore diameters smaller than 1 nm is the key to storing large amounts of hydrogen by physisorption.

1.2
Zeolites

Reversible occlusion of gases in zeolites is a well-known phenomenon, although little attention has been paid to their use as media for hydrogen storage. Weitkamp et al. [19] found a relationship between the amount of encapsulated hydrogen and the size of the exchanged cation in zeolite A. The number of zeolite cages per gram material was between $3.58 \cdot 10^{20}$ for NaA and NaX and $1.41 \cdot 10^{21}$ for sodalite, and the number of molecules H_2 per cage was between 0.1 and 0.25 for the different materials. Storage capacity was generally higher for zeolites having a high number of small cavities in their structure, and sodalite showed the highest hydrogen uptake of 9.2 cm^3/g (0.082 wt.%) when loaded at 573 K and 10 MPa hydrogen pressure. This implies that only one out of four to five sodalite cages was occupied by a hydrogen molecule. The reason why not every cage takes up at least one hydrogen molecule is unknown. If every cage in sodalite would contain a single hydrogen molecule, a maximum storage capacity of 54 cm^3/g or 0.48 wt.% could be expected.

The storage capacity can be increased substantially when loading zeolite samples at liquid nitrogen temperatures. Kazansky et al. [20] studied hydrogen adsorption on sodium forms of faujasite and found a hydrogen storage capacity of 1.2 wt.% H at 77 K. Moreover, a maximum hydrogen storage capacity of 1.81 wt.% (15 bar) was obtained for NaY zeolite in a recent study [21]. The authors noticed a close correlation between the BET surface area of the zeolite measured with nitrogen and the storage capacity for hydrogen at low temperatures. For all zeolites investigated, a type I isotherm was observed at 77 K, with desorption closely following the same path as adsorption. This indicates the process of microporous hydrogen physisorption in the zeolite structure at low temperatures.

A factor limiting the storage capacity of such systems certainly is the relatively large mass of the zeolite framework itself, which contains Si, Al, O, and heavy cations. Furthermore, many materials seem to have unnecessarily large diameters of their voids. A bottom-up design strategy to improve the storage capacity in microporous systems should therefore include

- a framework consisting of light elements.
- avoidance of nonessential free space in the structure.
- improving the interaction energy between hydrogen and the framework.

1.3
Metal-Organic Frameworks

Metal-organic frameworks (MOFs) are suitable systems for such a bottom-up approach. In their recent work on MOFs, Eddaoudi et al. [22] presented a synthesis strategy based on reticulating metal ions and organic carboxylate links into extended networks. The method uses a self-organizational process and allows for the design of porous structures, in which pore size and functionality can be varied systematically. MOFs are the lightest known crystalline materials with densities down to 0.21 g/cm^3 and have gained considerable interest because of their capability of storing in their framework hydrogen and light hydrocarbons, such as methane [23].

Figure 3(a) shows a cubic MOF structure of $Zn_4O(L)_3$ with Zn_4O clusters forming the corners and linked by linear carboxylates L. The building principle can be extended if other metalions, such as copper, or differently structured carboxylates are used. An example is shown in Figure 3(b), where the structure is formed by a trigonal carboxylate linking Zn_4O clusters.

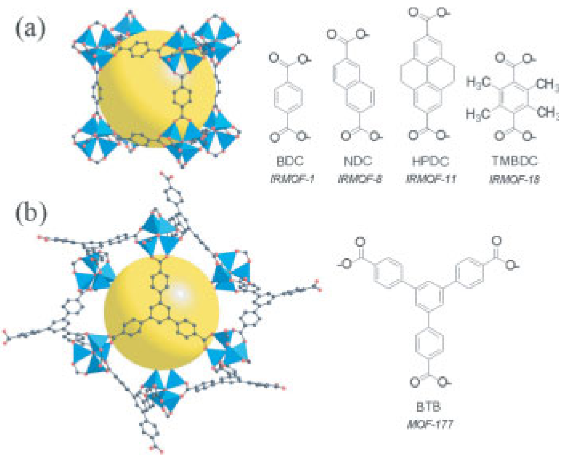

Fig. 3 (a) Metal organic frameworks, $Zn_4O(L)_3$, constructed by linking zinc oxide clusters with linear carboxylates L, such as those shown. (b) The structure of MOF-177, $Zn_4O(BTB)_2$, is formed by linking the same clusters with a trigonal carboxylate. The large void regions are illustrated by yellow spheres with diameters equal to the distance of separation between the frameworks' van der Waals surfaces (reproduced with permission from [24], Copyright 2004 Am. Chem. Soc.).

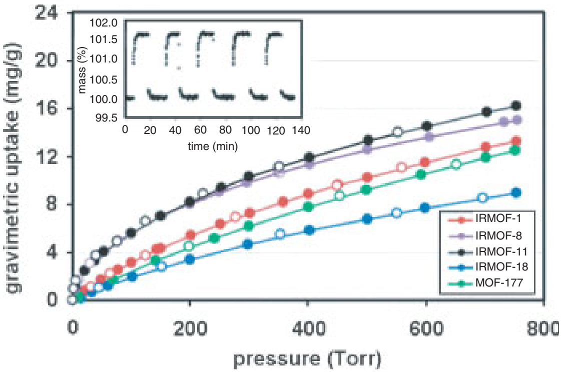

Fig. 4 Volumetrically measured hydrogen isotherms of the activated materials measured gravimetrically at 77 K (adsorption, ●; desorption, ○). The inset shows the time-dependent cycling of IRMOF-11 between 0 and 0.1 MPa of H_2 (reproduced with permission from [24], Copyright 2004 Am. Chem. Soc.).

Sorption isotherms for heavier gases in MOFs are of type I as is typical of microporous materials [24]. Their specific surface areas were calculated from nitrogen sorption isotherms with values ranging between 1466 m^2/g for IRMOF-8 (see Fig. 3a) and 4500 m^2/g for MOF-177 (see Fig. 3b). Isotherms for hydrogen adsorption in different MOF materials are shown in Figure 4. At 77 K and 0.1 MPa H_2 pressure, the maximum uptake of hydrogen was 1.6 wt.% for IRMOF-11. It is evident from this figure that the surfaces

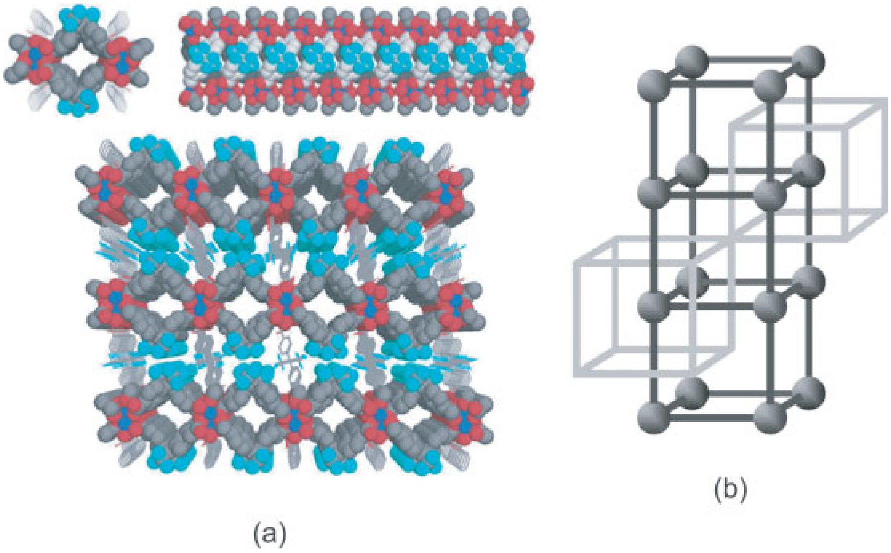

Fig. 5 (a) Structure of Cu-(hfipbb)(*H2hfipbb*)$_{0.5}$[*H2hfipbb* = 4, 4′-(hexafluoroisopropyl idene)-bis(benzoic acid)]. Top left: Cross section of a single microtube. (b) Schematic representation of an interpenetrating metal organic framework.

are not saturated by hydrogen at this pressure. Hence, the maximum uptake of each compound was not determined in the experiments. At room temperature and 2 MPa hydrogen pressure, the hydrogen uptake is about 1 wt.% [23].

Interestingly, there is a lack of correlation between the measured surface area and the hydrogen uptake. Apart from preparation effects, the nature of the organic linker was assumed to have a considerable influence on the number of hydrogen molecules attached to a linking unit [24]. This assumption is supported by the results of a theoretical study conducted by Hübner et al. [25] where the interaction energies of molecular hydrogen with different aromatic molecules were studied in ab-initio calculations. It was found that the binding energies between H_2 and differently substituted benzene rings vary systematically depending on the nature of the functional group. While electron-drawing groups lower the interaction energy, electron-pushing groups increase the values. Moreover, larger aromatic systems are superior to single benzene rings.

In the current state of the art, not much is known about the behavior of hydrogen in MOFs. Although the organic linkers seem to play an important role as binding sites, the role of the metal oxide clusters has not yet been elucidated. As the dynamics of hydrogen is another important factor, a critical aspect of pore quality is the relative size of the pores with regard to the hydrogen and its interaction energy with the pore's surface. As a design strategy, the pore diameters could be minimized to both increase the number of pores and the number of binding sites per volume, which would also enhance the volumetric storage density of the material.

For the practical implementation of the concept, other metal-organic frameworks with higher densities can be synthesized, an example was shown by Pan et al. [26] see Figure 5(a). Another approach is the synthesis of interpenetrating frameworks, as is shown in Figure 5(b). In this case, there would not be any limitation to using small linker molecules which might have less favorable properties concerning their interaction energy with hydrogen.

In order to provide for a spatial obstruction of the pores, Zhao et al. [29] synthesized nickel-based metal-organic frameworks with smaller channels and found that some of them exhibited a remarkable hysteresis in the adsorption and desorption of hydrogen at 77 K. 57 to 71% of the total pore volume of 0.149 and 0.181 cm^3/g H_2 were filled in two different structures with molecular-size windows. Of three different materials, the compound with the most distinctive isotherm hysteresis had the smallest window dimensions (smaller than the kinetic diameter of 0.29 nm of H_2) and cavities that were much larger than H_2.

Hysteresis decreases at higher temperatures and was therefore explained by kinetic trapping of the gas. This is supposed to result from the flexibility of the organic ligands (4, 4′-bipyridine) in the nickel-based MOF. It was assumed that desorption is kinetically limited at lower temperatures, so that hydrogen can be loaded at high pressures, but then stored at lower pressures.

1.4
Clathrates

Mao et al. [27] reported about a new type II hydrogen clathrate structure, where H_2 and H_2O mixtures crystallize at a pressure of 220 MPa and 250 K with an approximate H_2/H_2O molar ratio of 1:2. At higher temperatures, extremely high pressures are required to stabilize the material, e.g. 300 MPa at 280 K. The clathrate cages formed are multiply occupied, with a cluster of two H_2 molecules in the small cage and four in the large cage, see Figure 6. The quenched clathrate was found to be stable up to 145 K at ambient pressure. Raman spectroscopy revealed that the H_2 molecules in the cages still were in free rotational states. However, softening of the H–H stretching modes indicated increased intermolecular interactions between hydrogen and water molecules in the cage.

In a theoretical study, Patchovskii and Tse [30] essentially confirmed the experimental results and suggested that the stability of the clathrate was mainly caused by dispersive interactions between H_2 molecules and the water forming the cage walls. According to their calculations, the clathrate is thermodynamically stable at 2.5 MPa and 150 K.

Due to the high pressures needed for the formation of H_2/H_2O clathrates and their stability at low temperatures only, it would be favorable to further stabilize the structures and facilitate their formation. As a first promising result, Florusse et al. [28] showed that the presence of tetrahydrofuran as a guest component may indeed stabilize the clathrate at 280 K and 5 MPa pressure. PXRD measurements indicated that the same sII binary clathrate hydrate had formed as reported by Mao et al. [27] Obviously, the system is strongly sensitive to promoters, which gives room for further development.

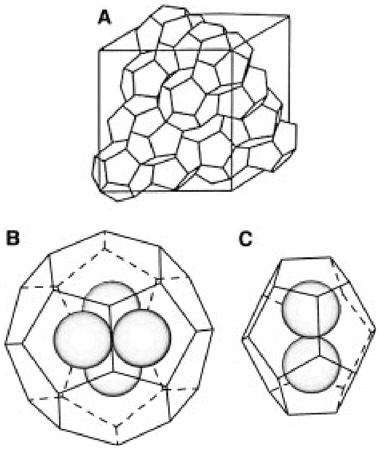

Fig. 6 The sII clathrate crystal structure consisting of $5^{12}6^4$ and 5^{12} building blocks. (B) A tetrahedral cluster of four hydrogen molecules in the $5^{12}6^4$ cage. (C) A cluster of two hydrogen molecules oriented towards opposite pentagonal faces in the $5^{12}6^4$ cage. The H_2O frameworks define the edges of the polyhedrons, with an oxygen atom at each corner and a hydrogen atom on each edge. The $5^{12}6^4$ and 5^{12} cages are drawn to scale relative to the enclathrated hydrogen molecule (sphere) of 2.72 Å diameter (reproduced with permission from [27], Copyright 2002, American Association for the Advancement of Science).

2
Hydrogen Storage by Chemisorption

The common way of storing hydrogen in solids is the chemisorption of dissociated hydrogen in noble metals [31] and alloys. This method is suited for obtaining high volumetric capacities due to the short hydrogen–hydrogen distances that can be realized in a hydride material. The minimum H–H separation in ordered binary metal hydrides is 0.21 nm, this limit being due to the repulsive interaction generated by the partially charged hydrogen atoms [32].

While the volumetric hydrogen density in transition metals and alloys is high, gravimetric density is inherently low due to the relatively high mass of the metal atoms (see Fig. 1). Consequently, systems consisting of light elements have moved into the focus of research and a new field has been opened up by investigating the reversible properties of complex hydrides $M^{+x}(BH_y)_x$, with M = Li, Na, K, Be, Mg, Ca,. . ., and B = B, N, Al. These so-called boranates, amides, and alanates are salt-like materials and consist of a cation

M^{+x} and a complex anion $BH_y{}^{-1}$, where the hydrogen atoms are covalently bound to the central atom B.

Nanoscale effects have been found for a number chemisorption materials. They are mostly related to:

1. The reversible hydrogen content,
2. The thermodynamic properties which define the theoretical working parameters of the material, i.e. the pressure/temperature combinations where hydrogen can be absorbed and desorbed, and
3. The kinetic properties that determine the rate at which hydrogen can be exchanged at a given temperature and pressure.

The following selected examples refer to these topics and were chosen in order to discuss recent findings and developments in this field. For further information, several excellent reviews on hydrogen in metals [33], intermetallic compounds [34, 35], and complex hydrides [36] can be found in literature.

2.1
Metal Clusters

Nanocrystalline metals and metal-hydrogen alloys with typical grain sizes of less than 20 nm possess many properties that differ from those of conventional coarse-grained materials. As an example, the thermodynamics of Pd-H clusters have been studied by several groups both theoretically and experimentally. Their hydrogenation behaviour was found to differ from that of coarse-grained Pd. Figure 7 shows isotherms of differently prepared Pd-H clusters of similar diameter, compared to bulk data [38]. The cluster data exhibit a remarkable increase in the hydrogen solubility in the solute solution phase (α-) and decrease in the hydride (α'-) phase, e.g. a considerable narrowing of the two-phase region.

Eastman et al. [39] reported that the entire volume of nanocrystalline samples was transformed to α'-PdH when exposed to hydrogen and suggested that the observed narrowing of the miscibility gap was due to different entropies and/or enthalpies of mixing in nanocrystalline and coarse-grained samples.

Pundt et al. [37, 38] proposed that an outer shell of the grains or particles would not participate in the phase transition, whereas the phase diagram of the core remains unchanged relative to that of the coarse-grained alloy. An enrichment of hydrogen at the surface is also supported by the results of Monte-Carlo simulations for hydrogen-loaded, multi-facetted Pd clusters of about 2 nm in size [40].

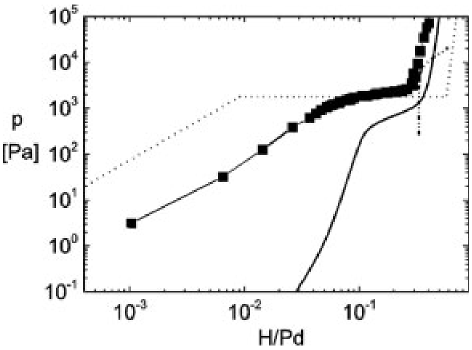

Fig. 7 Isotherms for Pd-H clusters of similar diameter (– compacted clusters d = 3.9 nm, 293 K, ■ quasi-free clusters d = 3.5 nm, 310 K, and bulk data (. . .) (reproduced with permission from [37], Copyright 2004, WILEY-VCH Weinheim).

Weissmüller et al. [41] showed that the observed lowering of the critical temperature was a function of the grain size [42] in Pd-H and the changes in the miscibility gap in the core could be explained solely by thermodynamic effects. It was found that hydrogen enrichment and depletion at grain boundaries of compacted nc $Pd_{81}Au_{19}$ result in a strongly size-dependent interface stress that is compensated by a pressure in the bulk [43]. Hence, long-range elastic interactions of grain boundaries and crystallites may shift the thermodynamic equilibrium in the crystallites and influence both the solubility and the total hydrogen content of hydrogen storage materials. As grain size decreases, interface stress must be taken into account for an appropriate determination of the hydrogen content from the lattice parameter and the prediction of the decrease in the critical temperature [44].

Thermodynamic effects were also observed in other materials, e.g. nanocrystalline $LaNi_5$ [46] and FeTi [47]. Here, an enhanced solubility of hydrogen at low pressures was found [48], similar to Pd. Moreover, the two-phase region of nc Fe-Ti is narrowed compared to coarse-grained FeTi.

2.2
Nanocomposites

For the preparation of nanocomposites, mechanical alloying has the advantage of simplicity as preparing technique which offers a free choice of various kinds of alloys [45, 48]. In addition, the technique allows for the mass production of non-equilibrium phases of alloys over a wide range of composition. It was also found that a number of difficulties in synthesis and processing of metal hydrides could be solved by applying this method.

In the first instance, improvements were made with respect to the so-called ''activation'' of hydride materials. This is a process, by means of which possibly present oxidic barriers at interfaces are broken by a mechanical treatment and high isotropic and anisotropic lattice strains are induced in the material so that a high density of dislocations in the order of $10^{12}\,\mathrm{cm}^{-2}$ is produced [49]. This promotes the transformation of the alloy, as a forming hydride phase may not coherently precipitate in a perfect lattice due to the large elastic energy associated with precipitation and the small formation enthalpy for hydrides. When a virgin sample of e.g. $LaNi_5$ is hydrogenated, hydride precipitation is considered to occur at free surfaces and at lattice defects that thread the surface where the elastic strain is largely relieved [50]. The formation of dislocations may therefore play a key role in the phase transformation during hydrogenation and dehydrogenation

A number of hydride materials that could be synthesized under severe conditions or in a complicated process only have been made accessible by mechanical alloying of the constituting elements. For example, the composition of raw materials is important when synthesizing $LaNi_5$, because La and Ni possess different melting vapor pressures. Moreover, the cooling process has to be controlled carefully to avoid a peritectic reaction and to obtain the product with the right composition. At the same time, the product can be produced easily by ball milling [51, 52]. A material synthesized in such a manner exhibits improved hydrogenation and dehydrogenation kinetics [53], see Figure 8. It was also shown that a nanocomposite produced by ball milling of the immiscible metals Fe and Mg exhibits better hydrogenation kinetics and reversible capacities for hydrogen than the same material produced by sintering [54]. Thus, the activation temperature for Mg_2FeH_6 could be lowered by 100–150 K.

A further developed method for the synthesis of ternary hydrides is reactive ball milling, where the primary materials are milled under a hydrogen atmosphere at elevated pressures. A hydride phase forms during the process, which is more brittle than the raw materials. It may facilitate the milling process and speed up synthesis. A number of complex and interstitial hydrides have been produced in this way, for example Mg_2FeH_6 [55], Mg_2NiH_4 [56], $TiFeH_x$ [57], and $Zr_{1-\delta}NiH_x$ [58].

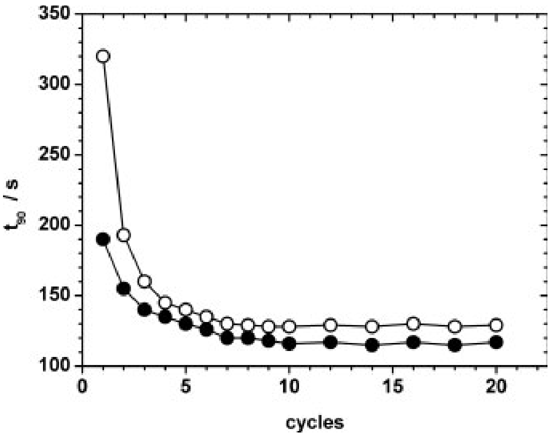

Fig. 8 Time of 90% of the hydrogenation reaction at room temperature versus the cycle for (●) the 5 h milled $LaNi_5$ powder, (○) the unmilled $LaNi_5$ powder (reproduced with permission from [53], Copyright 1999, Elsevier Science S.A.).

In a further attempt, Huot et al. showed that Mg_2FeH_6 can also be produced directly by mechanical alloying of the preformed hydride MgH_2 and Fe [59]. Synthesis of alkali metal and strontium alanates is feasible using the same principle according to Dymova et al. [60, 61] while adding a Ti-based dopant such as $Ti(OBu)_4$ [62] enhances the hydrogen exchange kinetics of the material produced. In addition, a number of solid-state reactions may take place in a ball mill to yield hydrides that can hardly be produced by other methods, such as: [63–65]

$$2\,\mathrm{NaH} + \mathrm{NaAlH_4} \longrightarrow \mathrm{Na_3AlH_6} \tag{1}$$

$$2\,\mathrm{NaH} + \mathrm{LiAlH_4} \longrightarrow \mathrm{Na_2LiAlH_6} \tag{2}$$

$$2\,\mathrm{NaAlH_4} + \mathrm{CaCl_2} \longrightarrow \mathrm{Ca(AlH_4)_2} + 2\,\mathrm{NaCl} \tag{3}$$

$$2\,\mathrm{AlH_3} + \mathrm{MgH_2} \longrightarrow \mathrm{Mg(AlH_4)_2} \tag{4}$$

A particular advantage of mechanical alloying is the opportunity to blend dopants with the hydrogen carrier materials, thus forming a nanocomposite and reducing kinetic barriers associated with hydrogen chemisorption and/or phase transformation. This is advantageous for practical use, as in some cases, e.g. in automotive applications, short refuelling times are needed, which can only be achieved when using such a nanocomposite. The following chapters address this emerging field in more detail, the focus being on a light metal hydride and alanates.

2.2.1 Magnesium Hydride

Magnesium is of particular interest to hydrogen storage applications because of its low costs and high content of 7.6 wt.% hydrogen. However, hydrogenation of untreated Mg is very slow and numerous attempts have been made to both increase the hydrogenation rate and decrease the desorption temperature of 573 K. This high temperature is mostly due to the high enthalpy of formation of −76 kJ/mol. On the other hand, these properties make magnesium hydride a favorable material e.g. for thermal and solar-thermal applications.

The absorption and desorption kinetics may be enhanced considerably by simple ball milling of pure MgH_2, and a correlation between the transformation rate and the grain size of Mg was reported by Zaluska et al. [66] Figure 9 shows that a freshly ball-milled Mg sample with a grain size of 1 μm is virtually inert to hydrogen, whereas material with grain sizes smaller than 50 nm can be hydrogenated to 80% of the theoretical capacity within 120 min only. Dehydrogenation curves of both unmilled and milled samples exhibit a sigmoidal shape, which suggests that a nucleation and growth process governs the transformation rate. The effect of milling was explained qualitatively by an increasing influence of grain boundaries and enhanced diffusion of hydrogen.

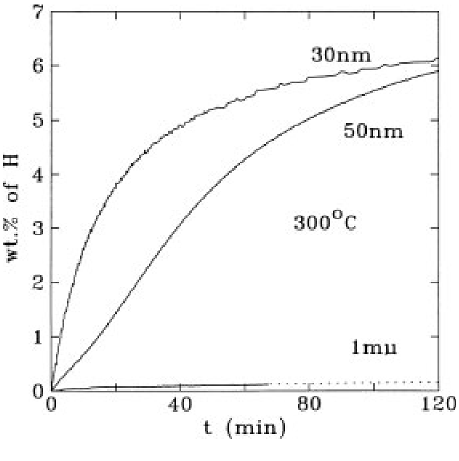

Fig. 9 Effect of grain size on hydrogen absorption of ball-milled magnesium powder: Absorption at 573 K, first cycle, no activation (reproduced with permission from [66], Copyright 2001, Springer-Verlag GmbH).

To further improve the H exchange kinetics, composite materials were prepared by ball milling of Mg with a series of transition metals either absorbing hydrogen (e.g. V, Nb, Pd, Pt[68, 69]) or not (e.g. Ni, Fe, Cu, Co [71, 70]). V, Nb, and Pd do not alloy with Mg, and small hydrogenated particles in the composite are supposed to act as gateways for the hydrogen to the magnesium matrix. For V- and Nb-doped nanocomposites, the dehydrogenation rate at temperatures below 573 K was again found to be limited by nucleation and two-dimensional growth. At higher temperatures, the reaction is interface-controlled, with a two-dimensional growth of the forming Mg phase [67].

Metal oxides may have a strong catalytic effect, even in small amounts, as was found for the oxides of Ti, V, Cr, Mn, Fe, and Mo [72, 73]. The role of the transition metals has not been settled yet, but the formation of hydrides was observed in the case of TiH_x and VH_x. They may act as a hydrogen donor [72]. Other oxides are known to incorporate hydrogen and form a bronze, such as H_xWO_3. Hydrogen bronzes provide for a high hydrogen mobility that might lead to a spillover effect in contact with Mg/MgH_2. However, the detailed mechanism is not known and subject of research at the moment.

2.2.2 Alanates

Due to their high storage capacity, aluminum hydrides or alanates have been considered promising materials for fuel cell applications. Alanates belong to the so-called complex hydrides and are composed of a "complex anion" $[AlH_4]^-$ or $[AlH_6]^{3-}$ and the respective cation. They are salt-like, insulating materials. The bond between the hydrogen atoms and aluminum can be regarded as covalent with a strong ionic character [75], the bond to the cation is ionic. Here, they differ from classical metal hydrides, where the H atoms are incorporated in tetrahedral and octahedral holes of a metallic host lattice. Nevertheless, similarities of both types of materials are observed in principle, for example when they are ball-milled and/or when dopants are added.

Several alanate compounds containing light cations have been investigated for hydrogen storage purposes 74, 76–78. Of these candidates, sodium alanate ($NaAlH_4$) currently is the most investigated and promising hydrogen carrier due to its high hydrogen content and auspicious thermodynamic properties. The pure macrocrystalline compound melts at 456 K and the melt starts to decompose and release H_2 at around 513 K, forming the hexahydride Na_3AlH_6 and elemental Al as solid decomposition products. Na_3AlH_6 decomposes at temperatures above 573 K and releases H_2 so that a mixture of two solid phases, NaH and Al, is obtained; see Eqs. (5) and (6). The decomposition of NaH occurs at temperatures above 723 K, which is considered too high for practical applications, the maximum reversible storage capacity for hydrogen therefore is 5.5 wt.% H [79]:

$$3\mathrm{NaAlH_4} \leftrightarrows \mathrm{Na_3AlH_6} + 2\mathrm{Al} + 3\mathrm{H_2}$$

$$(+\Delta H = 3 \times 37\ \mathrm{kJ/mol};\ 3.7\ \mathrm{wt.\%H}) \tag{5}$$

$$\mathrm{Na_3AlH_6} \leftrightarrows 3\mathrm{NaH} + \mathrm{Al} + 3/2\mathrm{H_2}$$

$$(+\Delta H = 47\ \mathrm{kJ/mol};\ 1.8\ \mathrm{wt.\%H}) \tag{6}$$

When the material is ball-milled, desorption already starts below the melting point of $NaAlH_4$, which is probably due to the lowering of kinetic barriers [80]. Although milling leads to such a pronounced effect, however, no thorough study has been performed so far to explain the reasons of this behavior. In particular, it is not yet clear whether the effect is caused by an increasing influence of interfaces and grain boundaries, by introduced defects, or by a combination of reasons.

A strong influence of doping agents was also found for the alanates. Bogdanovic and Schwickardi [74] discovered that the addition of small amounts of Ti compounds may considerably accelerate H exchange in $NaAlH_4$. Thus, working temperatures around 373 K can be achieved, which fits to the working conditions of a PEM fuel cell. A variety of metals have been tested as dopants in the meantime [74, 81] and Ti was always found to have the best catalytic activity for $NaAlH_4$. In the first work, Ti alkoxides were used in a wet impregnation process to form a finely dispersed layer of small Ti particles on macrocrystalline $NaAlH_4$. Later, it was shown that the simple addition of Ti alkoxides or halides to the alanate and ball milling of the mixture under inert conditions lead to improved kinetics and a simplification of the process 82–84. Another considerable increase in the transformation rate was achieved recently by using a solvent-stabilized Ti_{13} cluster as dopant [85, 86].

Figure 10 shows the isothermal hydrogen desorption behavior of different composite materials, as obtained from kinetic studies by Kircher et al. [87] The samples were prepared by ball milling of sodium alanate for 30 min under an argon atmosphere with different precursors and decomposed isothermally at 423 K. For comparison, the data of a ball-milled undoped sample are shown. The diagram reveals the slow decomposition of the undoped alanate despite the higher decomposition temperature of 443 K and indicates the advantage of using nanoscale Ti as a precursor in the doping process.

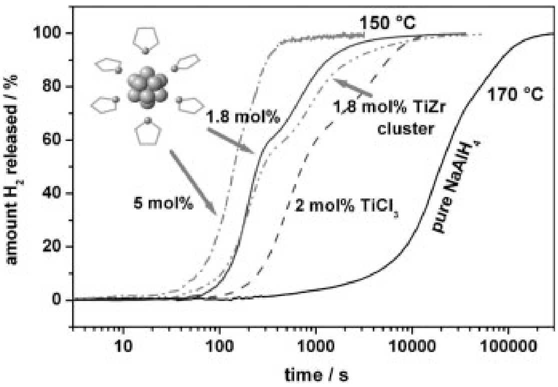

Fig. 10 Isothermal desorption behavior of different composite materials, all based on $NaAlH_4$ as hydrogen carrier, milling time 30 min. The doped samples were decomposed at 423 K in a vacuum.

A similar distinct improvement was observed for the rehydrogenation rates of dehydrogenated composites. Figure 11 shows the isothermal hydrogenation behavior after the third hydrogenation/ dehydrogenation cycle. As can be seen from the diagram, it was possible to refuel the material to 80% of the total absorption of about 4.5 wt.% H within only one minute, which would meet the refuelling time target of the US-DoE for 2015.

An interesting feature of both reversible transformation Reactions (5) and (6) is that a massive mass transport is involved, which covers distances in the range of up to 100 nm due to the grain sizes of the different phases. For illustration, Figure 12 shows a STEM of decomposed material after the 8th cycle, where the solid phases involved in the process have been identified by electron microscopy [89]. If such a decomposed sample is rehydrogenated, the separated solid phases NaH and Al have to establish a reactive interface to form Na_3AlH_6 in the presence of hydrogen. In the second step,

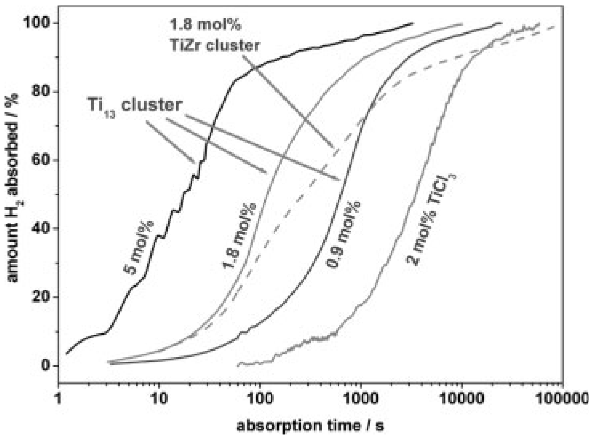

Fig. 11 Isothermal absorption behavior of differently doped alanate samples (milling time 30 min, absorption temperature 373 K, H_2 pressure 10 MPa).

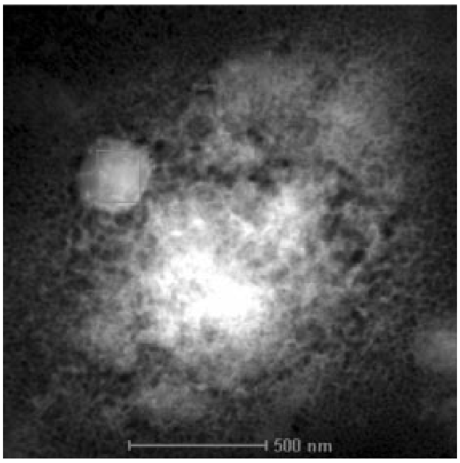

Fig. 12 STEM of $NaAlH_4$ doped with 5 mol% Ti clusters and desorbed after the 8th dehydrogenation/hydrogenation cycle. The encircled area contains a region of pure Al (white).

Na_3AlH_6 and Al react with H_2 and form $NaAlH_4$. Both reactions occur within minutes at temperatures around 370 K.

In order to examine the mechanisms underlying this process, the kinetics of the phase transformations were analyzed by a separate investigation of the various hydrogenation and dehydrogenation steps of Eqs. (5) and (6). For this purpose, a reactor and an experimental setup were used to minimize the effects of the reaction heat and thermal conductivity of the material [85, 87, 88]. As a result, the kinetic data of both absorption and decomposition curves could be fitted well over a wide range by applying a Johnson-Mehl-Avrami equation that describes the reacted fraction F when the rate-limiting process for the formation of the new phase is nucleation and growth (Eq. 7).

$$F = 1 - \exp\{-(kt)^{\eta}\} \tag{7}$$

The Avrami exponents η obtained were small and reflected diffusion-limited nucleation and growth of the new phase as a rate-determining step in the kinetics. In samples doped with higher amounts of Ti, the Avrami exponent changed during absorption, probably due to overlapping diffusion profiles of neighboring grains.

Several suggestions were made to explain the accelerating influence of Ti dopants on the transformation of the composites. It was proposed for example that Ti might facilitate the formation or decomposition of potentially mobile AlH_3 at grain boundaries and AlH_3 could transport the aluminum over larger distances [90]. As this species has not been detected up to now, more work is needed to prove or disprove the existence and potential role of AlH_3.

It was also proposed that Ti metal, a solid solution of Ti in Al, or a Ti-Al alloy is catalytically active at the surface of doped, ball-milled alanate. There, it could act as chemisorption site for the dissociation or recombination of molecular hydrogen. Indeed, chemisorption of H_2 on Ti-doped $NaAlH_4$ was found in isotope scrambling experiments [36] and Ti-Al phases were detected by EXAFS and XRD measurements 91–93. However, it is not clear at the moment whether chemisorption at the Ti-containing phases plays a decisive role in the kinetics. An addition of $TiAl_3$ as dopant and ball milling led to a slight improvement of the reaction rates only [91], but a certain influence cannot be excluded and further work is necessary to elucidate the role of these phases.

Another hypothesis proposed by Fichtner et al. [94] is based on the kinetics of the phase transformations and on data obtained with different dopants. As shown above, the rate-limiting steps of the phase transformations of sodium alanate and the associated hydrogen absorption or desorption are governed by nucleation and growth processes which are limited by the diffusion of the phases involved. Therefore, it was concluded that Ti-based dopants must have an accelerating influence on exactly these steps. A potential role of Ti in the acceleration of the transport processes could be the reduction of activation barriers for the mobility of atoms, e.g. by introducing defects. In fact, recent studies indicate that Ti may indeed exchange with Al in the alanate lattice, thus creating non-thermal defects and vacancies due to the differences in size and charge of the atoms. According to density functional calculations by Lovvik and Opalka [95], for example, Ti may replace Al close to the surface, thus leading to a metastable state of the system.

Apart from this potential function of the dopant, NMR experiments revealed that the mobility also of H atoms was enhanced in the nanocomposite after doping [96]. Provided that all these steps are necessary for the overall transformation reaction, it is likely that the process is a consecutive reaction of fast chemisorption and hydrogen diffusion steps and slower, rate-limiting diffusion processes in the solid. This would also explain why noble metal catalysts that have much better chemisorption capabilities than Ti were found to have no advantage for alanate materials – because they cannot exchange with Al in the lattice and the chemisorption step already is faster than the material transport. Recent studies of isotope effects in the rate limiting steps of the materials transformation suggest a species heavier than H as being the mobile species [106]. The data rather supports species such as Al_xH_y which could be responsible for the Al transport.

It should be mentioned that quantitative information about the different transformation steps in the nanocomposites is still lacking. Consequently, the conclusions drawn above are of preliminary character only. Again, more mechanistic work is needed in order to learn more about the details of hydrogen exchange and the role of the dopants in these materials. The outcome will be essential for the further development of the alanates as hydrogen storage materials.

2.2.3 Other Complex Hydrides

Other complex hydrides containing light elements, such as the boranates and amides, have a very high gravimetric hydrogen content of up to 18.4 wt.% ($LiBH_4$). First studies of their reversible hydrogen storage properties have been published in literature. Although promising because of their high hydrogen content, however, the boranates exhibit a high thermodynamic stability due to the strong B–H bond, and the working temperatures and pressures achieved in dehydrogenation/hydrogenation experiments are too high for current PEM fuel cell applications [97]. Furthermore, it is known from early works on boranates that volatile boranes may develop upon the decomposition of the solid. The gases are toxic and may poison the catalytic membranes of the fuel cell. Future work in this field will therefore be aimed at finding ways of destabilizing the complex hydride and avoiding the production of boranes. $Mg(BH_4)_2$ is one of the few complex hydrides which have the potential to meet the requirements for hydrogen storage materials, because it contains 14.9 mass% H and has suitable thermodynamic properties. It can be synthesized by various methods and is currently investigated for hydrogen storage applications ([107] and references therein).

In search of other systems for hydrogen storage, Chen et al. [98] presented a work on the reversible hydrogenation behavior of lithium nitride which transforms stepwise, similar to the alanates:

$$Li_3N + 2H_2 \leftrightarrows Li_2NH + LiH + H_2 \leftrightarrows LiNH_2 + 2LiH \quad (8)$$

The amount of H_2 absorbed at Li_3N is 10.4 wt.% in this reaction, which is a very high value. However, the overall heat of reaction is −161 kJ/mol and operation temperatures above 520 K were reported, which is a daunting value for low-temperature fuel cell applications. Nonetheless, successive activities have led to an interesting and promising new approach, as will be shown in the next chapter.

2.2.4 Combined Systems

Shortly after the work of Chen et al. [98] other groups presented their work on amide systems [101, 102]. Ichikawa et al. [99] pointed out that the enthalpy change of the second reaction of Eq. (7) is −44.5 kJ/mol only, which is almost ideal from the thermodynamic point of view, because the free enthalpy of reaction is close to zero at room temperature. To perform the reaction, they produced composite materials containing $LiNH_2$ and LiH by ball milling and investigated the hydrogenation/dehydrogenation behavior according to Eq. (9), with a theoretical amount of 6.5 wt.% H being involved.

$$Li_2NH + LiH + H_2 \leftrightarrows LiNH_2 + 2LiH \quad (9)$$

Small amounts of $TiCl_3$ as dopant were found to have a strong accelerating effect on the reaction and it was suggested that it might act as a transfer agent for intermediate NH_3 to LiH. In a subsequent work, it was stated that the uniform

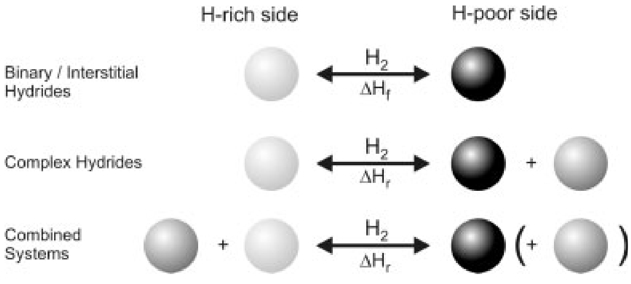

Fig. 13 Solid phases involved in the hydrogen exchange of different classes of storage materials.

distribution of nanometer-sized Ti metal between LiH and $LiNH_2$ plays an important role for the catalytic effect [100].

Compared to the binary and interstitial hydrides and the alanates, reactions of the type of Eq. (9) open up a new field in the development of hydrogen storage materials. For illustration, a simplified classification scheme of hydride systems shows a distinction of three classes with increasing degree of complexity, see Figure 13. The first class of systems includes the binary and interstitial metal hydrides, where the reaction enthalpy is the same as the enthalpy of formation and basically one H-rich and one H-poor solid phase are involved in the transition. The next, more complicated situation is found for metal hydrides, including the alanates, where one H-rich and two H-poor phases are involved. Finally, the novel, combined systems consist of two H-rich and one or two H-poor phases. The systems may be considered solid-state reactions of binary (or interstitial) metal hydrides with complex metal hydrides, under the exchange of hydrogen.

Even though this is an additional degree of complexity, the approach provides for a number of opportunities to design a storage system. In principle, many combinations of binary and complex hydrides are conceivable, so that an optimization can be made with respect to the exchangeable amount of hydrogen and the thermodynamics, i.e. reaction enthalpy and reaction entropy. Even compounds with originally unfavorable thermodynamic properties for low-temperature fuel cell applications, such as MgH_2, may be considered again when combined with an appropriate reaction partner. An example was published recently by Luo [103] where a nanocomposite was prepared by high-energy ball milling of a MgH_2:$LiNH_2$ mixture with a molar ratio of 1.1 : 2. The reversible behavior of the material was tested at temperatures between 473 K and 573 K and 6–6.5 wt.% H were gained upon absorption and desorption. At 473 K, hydrogen absorption took place at 3.2 MPa hydrogen pressure. Leng et al. [104] investigated a composite material produced by ball milling of a 3 : 8 molar mixture of $Mg(NH_2)_2$ and LiH under a 1 MPa H_2 atmosphere. The results showed that a large amount of hydrogen (approx. 7 wt.%) started to be desorbed at 413 K, and desorption peaked at 463 K. Hydrogenation was achieved, e.g. at 473 K and 3 MPa H_2 pressure. Based on X-ray diffraction measurements of the material in different stages, the following reversible reaction was proposed (Eq. 10).

$$3Mg(NH_2)_2 + 8LiH \leftrightarrows Mg_3N_2 + 4Li_2NH + 8H_2 \qquad (10)$$

The challenges associated with this new type of systems are the number of solid phases that are involved in the transformations. At lower working temperatures, severe kinetic barriers may interfere with the phase transformations and, therefore, with the H exchange. In any case, a transport in the solid and an interface reaction are necessary and means like

- shortening the diffusion path,
- enhancing the mobility, e.g. by introducing defects, and
- an intimate contact along the reactive phase boundaries

may be considered prerequisites for a properly and fast working system. All these requirements are influenced by the particle size and structure of the grain boundaries.

Accordingly, a nanotechnological approach is deemed advantageous for the development of this promising new type of systems.

3
Conclusion

Hydrogen storage in solids is, in the medium and long term, considered to be one of the most promising and challenging methods for the realization of hydrogen storage systems in fuel cell-driven mobile applications. Recent advances have given rise to the hope that the targets defined for 2010 or even 2015 could be reached, provided that the progress made in the different areas can be continued. A particular challenge is the combination of targeted storage capacities, thermodynamic properties, and hydrogen exchange kinetics of storage materials, thus opening up a multi-faceted research field that makes the use of a multidisciplinary and interdisciplinary approach mandatory. Recent developments have shown that a nanotechnological approach may be very effective in this field, because it combines physics, chemistry, and engineering science and closely looks at the microstructure of materials, thus giving clues for a tailor-made development by optimizing the bonding environment for molecular or atomic hydrogen.

Nanotechnology: An Approach to Mimic Natural Architectures and Concepts

Pierangelo Gröning

1
Introduction

Most of the revolutions in the industrial evolution of the past 250 years were to a good extent accompanied by the abilities to produce smaller and smaller devices with higher and higher precision. In a historical perspective one will observe that the rate at which this ability to miniaturise structures has rapidly increased in the past 40 years. From the early ages of mankind on to the beginning of the antique cultures around 3000 B.C. the relevant scale of material processing was the meter down to the centimeter. Then, skilled craftsmen developed routes for fineries, e.g. by manufacturing metals with millimeter features. Despite the continuous decreasing tolerances in the machining, the millimeter remained the relevant scale of the smallest features in material processing till the second half of the last century. The step to the micrometer was taken in the 1970ies with the development of the semiconductor technology. From then on it took less than 30 years to extend materials processing to the nanometer range. Thus, mechanical engineering, electromechanics, micromechanics, electronics, microelectronics developed successively. Today, it is possible to fabricate micro-electromechanical systems (MEMS) of several hundred nanometers in size with few nanometers tolerance. Recent microprocessors exhibit gate structure widths of 90 nm only. Manufacturing these very small structures demands tremendous precision and stability on the lithography process and, consequently, on all the optical and mechanical elements and the construction of the production tools. For example, the thermal expansion of the mask material for photolithography (ceramics) must be below 0.1 nm or one atomic diameter per centimeter and degree Celsius – a requirement which lies at the physical limits. This example shows clearly that industrial production techniques have penetrated deeply into the nanometer scale.

We are certainly aware that chemistry has been working with nano-objects for several hundred years. Here, we want to highlight the advances in processing individual objects though, which would be called the top-down approach in contrast to the bottom-up approach delivered by chemistry. It might seem that nanotechnology is just the natural consequent step in the continuous process of modern industrialisation. However, nanotechnology is much more than only the next stage of the miniaturisation process following microtechnology. An additional and central aspect of nanotechnology is that by shrinking objects to nanometer dimensions their physical properties start to differ markedly from macroscopic, in fact even from the microscopic ones. Actually, the nano-objects reveal their discrete, atomistic structure and the description of phenomena on this scale in terms of classical physics is not valid any more, that quantum effects not only become important but dominant.

The invention of the Scanning Tunnelling Microscope (STM) in 1981 by *G. Binnig* and *H. Rohrer* [1, 2] at IBM Rüschlikon, opened the gate to the nanoworld. With the STM and the later invented Atomic Force Microscope (AFM) [3] it became possible to visualise and handle individual atoms and molecules, in short STM and AFM may be addressed as a "*Feynman* Machine" – *"The principles of physics, as far as I can see, do not speak against the possibility of manoeuvring things atom by atom"; R. P. Feynman*, 29. Dec. 1959 [4]. The prospect to control matter on molecular and atomic level fascinates many physicists, chemists, biologists and engineers worldwide to work on nanoscience and nanotechnology. In the approach to control matter on the ultimate level of molecules and atoms, many disciplines of classical science such as physics, chemistry, materials engineering but also biology and medicine meet on the nanoscopic scale. As a matter of fact, the biological and medical aspects of nanotechnology should especially be highlighted, since nature does nanotechnology at its best with proteins as nanomachines performing highly complex tasks with great efficiency.

2
Physical Benefits of Nano-particles

Breaking a macroscopic piece of matter into ever smaller parts, results first in an increase of the specific surface area, which is inverse proportional to the average diameter of the particles. Due to this, at first glance inconspicuous effect, nano-powders reach enormous specific surface areas in the order of 100–1000 m^2/g (Fig. 1). This makes nano-powders very interesting for applications involving surface reactions,

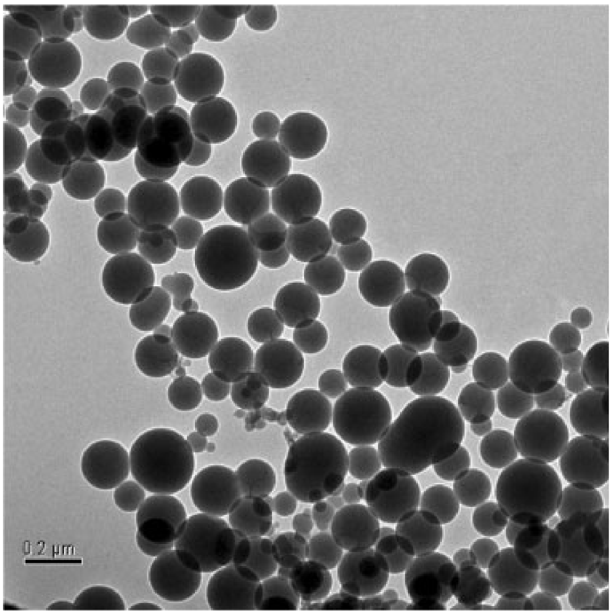

Fig. 1 TEM picture of non-aggregated spherical SiO_2 nano-particles produced by flame synthesis. (A. Vital, EMPA, Laboratory for High Performance Ceramics)

e.g. catalysts, membranes, filters or electrochemical double layer capacitors, often called super- or ultra-capacitor, will profit from a much extended efficiency by high surface area materials. The electrochemical double layer capacitor (EDLC) utilizes the double or *Helmholtz* layer formed at the electrode/electrolyte interface (Fig. 2) to store electrostatic energy. The electric charges accumulated on the electrode surface and the ions of opposite charge arranged on the electrolyte side of the interface form an electric dipole of an extremely small size of few nanometers. In first approximation, the capacity of the EDLC is given by the simple formula of the plate capacitor:

$$C_{Helmholtz} = \frac{\varepsilon_0 \cdot \varepsilon_r \cdot A}{d} \qquad (1)$$

where A is the apparent electrode surface, d the thickness of the dipole layer and ε relates to the dielectric constants. The specific capacity (C/A) of an EDLC is in the range of 5–50 $\mu F/cm^2$. In other words, an EDLC consisting of 100 g active electrode material with a specific surface area of 1000 m^2/g has the extremely high capacity of about 1 Farad. In comparison, a plate air capacitor with 1 mm electrode distance would have electrodes of 10,000 m × 10,000 m in size in order to produce the same capacity.

Reducing the particle-size does not only lead to an increase of the specific surface area, which would be a purely geometrical effect. Particles with sizes below 100 nm show a much reduced scattering of visible light, due to suppressed refraction. Therefore, nano-particles are practically invisible in dilute emulsions, which make them very interesting for applications as transparent, protective layers, e.g. scratch-proof lacquer for automotives, UV-light protection lacquer, sun-lotion or on ink-jet paper for photo quality printing. Since 2003, ''Mercedes-Benz'' cars can be ordered with a new type of clear lacquer containing ceramic nano-particles (Fig. 3). ''DaimlerChrysler'' promises that the nano-particles provide a three-fold improvement in the scratch resistance of the paintwork and ensures visibly enhanced gloss over an extended period of time [6].

When the particle size becomes extremely small, one has to realize that the number of surface atoms becomes comparable or even larger than the number of bulk atoms. In such situations the physical properties of the particle may be dominated by the properties of the surface atoms, which often differ from those in the bulk. As a classic example, the melting point of Au-clusters decreases from 1300 K to 300 K (room temperature!) if the cluster diameter decreases from 25 nm to 2.4 nm. The decrease in the average coordination of the gold atoms leads to a decrease in cohesive energy. For semiconductor particles with sizes below 10 nm the *de Broglie* wavelength of the electrons becomes comparable to the particle size. In this situation quantum confinement leads to a discretization of the valence electron state comparable to the textbook problem of an electron in a spherical box. The energy of the electron states depends on the particle diameter d as $E \sim 1/d^2$. A further result of the small particle size is that the momentum conservation in electronic transitions is lifted; in combination with the discrete level spectrum of the electron states, semiconductor particles may become fluorescent with colors depending only on the particle size (Fig. 4).

Silicon, macroscopically an indirect bandgap semiconductor is changing to a direct bandgap semiconductor as nano-crystal. Pavesi et al. [7] sandwiched silicon nano-crystals (ϕ = 3 nm) between layers of oxidized silicon. They tested them for optical gain by pumping with green laser light

(λ = 390 nm), while a second test laser shone through the sample. They observed amplification of the test beam in the red-infrared range with a peak at ~ 775 nm of the same order of magnitude as seen in gallium arsenide solid-state lasers.

Carbon nanotubes (CNTs) are considered as maybe the most famous objects in nanotechnology. The reason for this fame might be seen in a combination of several favorable circumstances. Firstly, CNTs represent a materials class with extraordinary properties in virtually every field of technological interest, be it mechanical, electronic, thermal, structural or optical. All these extraordinary properties arise truly from their nanoscopic dimensions and are markedly different from bulk graphite. Secondly, although being true nano-objects the CNTs are nanoscaled only in two dimensions. In the third

dimension they remain micro-objects that can be handled with our conventional microtechnology. Thirdly, CNTs can be produced in relevant quantities using relatively simple processes and, therefore, they have a good availability. CNTs are macromolecules composed only of carbon atoms, discovered in 1991 by S. Iijima [8]. They can be viewed as a graphene sheet rolled into a cylinder and seamlessly welded together. Tubes consisting of a single graphene layer are called single-walled nanotubes (SWNT) and tubes consisting of multiple, concentric layers are called multi-walled nanotubes (MWNT). Typical dimensions of the CNTs are one to several nanometers in diameter and length up to several micrometers. Their applications arise from the remarkable properties of SWNT such as ballistic electron transport as phonon scattering is efficiently suppressed, highest thermal conductivity (3000 W/Km), highest Young's modulus, and the high aspect ratio structure. The high electric conductivity in combination with the aspect ratio makes CNTs very interesting as fillers for conductive ceramic or polymer composites. From percolation theory it is known that a mixture of conducting and insulating particles becomes conductive when the volume fraction of the conducting particles exceeds 16%. This value is size- but not shape-independent. For CNT with their high aspect ratio, the chance of contact increases and conduction can occur at lower volume fraction of the conductive particles. Sandler et al. [9] achieved in MWNT-epoxy composites percolation at loadings smaller than 0.01%. A very interesting application of CNT-polymer composites is electromagnetic shielding or antistatic coating. Because SWNTs have the highest *Young*'s modulus of about 1 TPa if normalized to their diameter, all types of CNTs have attracted much interest for low weight structural composites. The incorporation of SWNTs has been demonstrated to significantly improve the mechanical properties of composites; SWNT reinforced composites with extremely high *Young* moduli and tensile strengths have been reported [10–13]. S. Kumar et al. [14] have shown that 10 wt% SWNTs added to poly(p-) phenylene benzobisoxazole increases the tensile strength by about 50% in comparison to the pure polymer and reduces the shrinkage as well as high-temperature creep. It is worth noting that the mechanical properties of the CNT-polymer composites strongly depend on the ability to homogeneously disperse them throughout the matrix without destroying their integrity. The main difficulties to disperse an adequate level of CNT into a polymer matrix are: the insolubility of the material and thus the relatively weak chemical bond between the CNT and the polymer. Functionalisation of the CNT surface to improve the according with the polymer is a challenge.

Several methods have been developed to synthesise CNTs. All of them, namely, arc evaporation [15], laser ablation [16], chemical vapour deposition (CVD) [17], and plasma enhanced chemical vapour deposition (PECVD) [18, 19] need metal particles (e.g. Fe, Co, Ni) for the catalytic growth reaction and elevated temperatures ($T > 600\,^\circ C$). The catalytic synthesis of CNTs has its origin in the corresponding early works on carbon fibers [20, 21]. Backer and Harris [20] proposed a model for the catalytic carbon filament growth in which the hydrocarbon precursor is decomposed on the surface of the catalytic metal particle. Dissociated carbon dissolves into the particle and diffuses through the particle to be precipitated on the trailing face, forming the carbon filament. The dissociated reactive hydrogen keeps the metal particle surface catalytic active by reducing oxides. The application of this model to CNT has been demonstrated recently by imaging the CNT growth process by in-situ transmission electron microscopy [22].

The world-wide production capacity for CNTs is estimated to around 50 tons per year and will be doubled in two years. Thomas Swan & Co. Ltd. launched in April 2004 at Consett (UK) the first commercial CNT plant in Europe [23].

3
Micro- and Nano-Structured Surfaces

In the previous section we have looked at particles and the consequences of reducing their size to nanoscopic dimensions. Now we will focus our attention on the question what can be gained by producing nanoscopic structures on surfaces.

Nature makes use of submicron structured surfaces in manifold manners, e.g. to keep leaf surfaces clean, or to achieve unique optical effects. In Asian culture, the lotus flower is regarded as the symbol of cleanliness. This, because the lotus leaf exhibits self-cleaning, nicely illustrated by the series of environmental scanning electron microscope (ESEM) pictures shown in Figure 5. The Pictures 5a and 5b show the clean lotus leaf's surface, which is covered with cones of $\sim 5\,\mu m$ in diameter and roughly $5\,\mu m$ in height.

These cones are again covered with fine hairs less than 100 nm in diameter and 0.5 μm in length. By increasing the relative humidity in the ESEM one can observe that water condenses first at each cone on the leaf surface forming small micron sized droplets. These droplets stick rather strongly to the cones, which enables them to lift up dust particles present on the surface (Fig. 5c). Further condensation increases the water droplet size till they merge forming a macroscopic droplet heavy enough to run off from the slightly vaulted leaf, taking with them every dust particles (Fig. 5d). This so-called lotus effect has already been used in a range of products, e.g. as "anti-graffiti" spray or self-cleaning textiles.

South-American butterflies from the Morpho family appear from specific angles as vivid blue and green metallic lustrous but rather dull brown under others angles (Fig. 6a). This vibrant play of colours displays attractive behaviour of the butterfly, resp. simultaneously serves as a camouflage. Whereas the majority of insects uses pigments (absorption) or occasionally thin film multilayer structures (interference) to create colours, the wings of the butterflies from the Morpho family have a complex 3-dimensional arrangement of submicron grating structures. The physical principle behind this unique visual effect is zero-order diffraction [24, 25]. Light incident perpendicular on a fine grating structure is typically diffracted into a number of grating orders at angles θ_n given by the *Bragg* relation $\sin\theta_n = n\lambda/d$, where λ is the wavelength of the light, $n = 0 \pm 1\ldots$ and d the grating period. At zero diffraction order ($n = 0$) light is transmitted

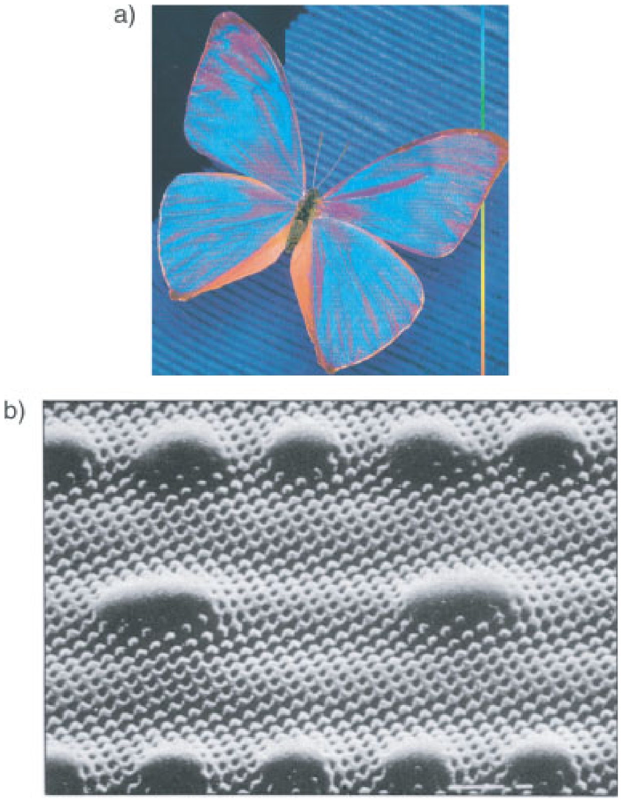

Fig. 6 (a) Butterfly from the Morpho family. Underneath, a SEM picture showing the submicron relief structure of its wings period (from[27]). (b) SEM picture of data written on the optical disk using moth eye antireflection structure (λ = 250 nm) (“Plasmon Data System”).

or reflected undeviated (independent of wavelength). If the grating period is finer than the wavelength no first order exists for illumination normal to the grating plane. Submicron gratings exhibit a strong polarisation dependence of reflected and transmitted light of wavelengths greater than the grating period, making zero-order diffractive optical elements an obvious candidate for polarisation applications. In contrast to holograms, zero-order optical structures can be viewed even under diffuse illumination, which makes them very interesting as security features. Zero-order optical structures based on embossed relief gratings, coated with a dielectric medium and fully integrated into a plastic sheet, are inherently more secure than holograms and, nowadays, widely used security feature on credit cards, banknotes, etc.

The night moth uses zero-order optical structures in a different way. The structure of its eyes is covered with a crossed grating microrelief with a period of about 250 nm. This structure acts as an antireflection layer at visible light by introducing a smooth, gradual change in the effective refractive index from the cornea to air, the eyes become less visible, and thus the whole moth to predators at night [26]. This moth eye antireflection structure has been investigated as an efficient absorber for thermal solar panels. The English Company “Plasmon Data System” developed an optical data storage disk based on the moth eye antireflection structure (Fig. 6b). The polycarbonate disk is covered by a uniform two-dimensional grating relief of about 250 nm period with a thin platinum layer on top. The structure is designed to have a low reflectance in the near infra-red. Data is written by heating the surface with the focused beam from a semiconductor laser, causing the formation of micron-sized bubbles with higher reflectance. The main technological advantage to create antireflection surfaces by optical microstructures instead of thin multilayer coatings is that the first can be produced very cheaply on a large scale by roll embossing into polymer foils or injection moulding.

Advanced technologies do not only allow copying natural structures, they are also able to produce nanostructures with applications not known in nature. Examples are the carbon nanotubes (CNTs) and their applications in vacuum micro-electronics. In opposition to the well established solid state microelectronics, which relies on the scattering dominated drift of electrons (or holes) in the conduction band (valence band) of a semiconductor such as silicon, vacuum microelectronics makes use of the collision free, ballistic motion of electrons in vacuum. The advantage of using a semiconductor as transport medium for electrons resides in the fact that the energies required to promote an electron from the valence band into the conduction band is in the order of 1 eV and, therefore, much lower than the work function ϕ, the energy required to put an electron from solid into vacuum which is usually in the order of 4–5 eV. Using doped semiconductors, the activation energy to produce carriers in the conduction band can be reduced further to a few meV, which makes it possible to have a saturated carrier concentration even at room temperature. Yet, the motion of electrons in a solid involves also some important disadvantages. On account of the collision dominated motion of the electrons in the conduction band the drift

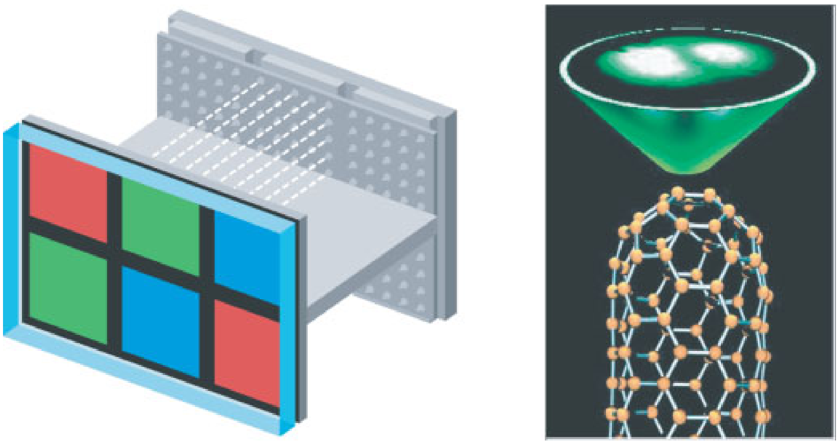

Fig. 7 (a) Sketch of 6 pixels of a Field Emission Display (FED). Each pixel on the screen is illuminated by about several hundreds electron emitters. (b) Schematic illustration of single CNT field emission pattern of a SWNT.

velocities are considerably smaller than for ballistic motion in vacuum at comparable electric fields. Furthermore, power is dissipated due to the interaction of the electrons with the lattice. Especially for high power and high frequency applications this power dissipation becomes a problem, because in the field of high power radio frequency and microwave amplifiers, vacuum electronic devices such as electron tubes, magnetrons or klystrons are still being used. In these devices the free electrons are usually generated by thermionic electron emitters. Albeit rather inexpensive and delivering high current densities, thermionic electron sources have a number of significant drawbacks: The large heat dissipation causes rather large energy consumption and, most important, the thermionic electron sources can neither be made very small nor be turned on and off at high frequencies. The term ‘‘small’’ here refers to length scales in the order of micrometers. Field electron emission from solids may open the door for the miniaturisation of electron sources. However, it was not until two decades ago that improvements in micro fabrication techniques triggered progress in manufacturing devices with miniaturised electron sources. These are commonly called vacuum microelectronic devices (VMED) and make use of a large number of micronsized field emitting electron sources. A device design based on a large number of parallel operating micron-sized electron sources can offer interesting technological applications, e.g., high power radio frequency amplifiers, electron guns for klystrons or travelling wave tubes, parallel e-beam lithography, or data storage where field emitted electron beams are used to read and write bits of data into a storing medium [28–31]. And perhaps in just a few years, we will find flat-screen televisions hanging on our walls, the working principle of which is based on the use of CNT as field electron emitter [32–34].

How is it that CNTs have found their way into the multibillion dollar application of flat panel displays? This stroke of luck is due to the fact that the first observation of their unique properties as electron emitter coincided with the development of a new field emission display (FED) technology in the second half of the 1990ies (Fig. 7). FEDs work like the conventional cathode ray tubes, except that each single pixel is illuminated by its own addressable, miniaturized electron source, which is directly located behind it. This arrangement allows displays to be made of only a few millimeter thickness still having the same outstanding image quality as cathode ray tubes. Classical cathode ray tubes use thermionic electron sources operating at temperatures between 950 and 2000 °C, making miniaturization impossible. In contrast, field electron emitters operating at room temperature hold great potential for miniaturization.

In 1928 R.H. Fowler and L.W. Nordheim [35] delivered the first generally accepted explanation for the electron field emission in terms of the newly developed theory of quantum mechanics. According to the Fowler-Nordheim theory, the field emission current density j is a function of the electric field E and the emitter work function ϕ according to following equation:

$$j = \frac{e^3}{4(2\pi)^2\hbar\phi} E^2 \exp\left(-\frac{4\sqrt{2m_e}}{3\hbar e E}\phi^{1.5}\right)$$

Fowler–Nordheim Relation (2)

The large electric fields of ~ 3000 $\mathrm{V\mu m^{-1}}$ required for electron emission from a flat surface can hardly be achieved, but can be generated by the field enhancing properties of tip-like structures. The field enhancement at the apex of a needle-shaped object of height h and radius r is in first approximation equal to the aspect ratio h/r [36]. A CNT with a diameter of 10 nm and a length of 2 μm exhibits, therefore, a field enhancement factor β up to 400. Therefore the required electric field E of 3000 $\mathrm{V\mu m^{-1}}$ for field emission can be generated at the CNT apexby a relatively low applied electric field $E_0 = E{\cdot}\beta^{-1}$ of 7.5 $\mathrm{V\mu m^{-1}}$.

The development of field emission electron sources has been hampered for half a century by the fact that tip-like field-enhancing structures are needed to locally create the high electric fields. Usually the higher the field enhancement factor β is, the smaller the effective emission area of the tip becomes, as the radius of curvature decreases. Although the field emission current density can easily exceed 100,000 $\mathrm{Acm^{-2}}$, the total emission current per single tip remains small as the emitting area, being the apex of the enhancing tip, is small. The current per single tip in field emission rarely surmounts 0.1 mA. As a result, field emitters are only used where high brightness rather than high currents are required, as it is in the case of high resolution scanning electron microscopes.

The key for reaching field emitter electron sources of high current density approaching 1 $\mathrm{Acm^{-2}}$ is in the integration of a large number of field emitters. Depending on the required emission current density, the density of the emitting tips has to be up to 10^8 $\mathrm{cm^{-2}}$. This limits their size to micron or even submicron dimensions. Today there is only one mature technology to produce field emitter arrays. This technology is the so-called *Spindt* type metal microtip process [37, 38]. The drawbacks of this technology are the expensive production, the critical lifetime in technical vacuum conditions, and the high extraction voltage. CNTs can be regarded as the potential second-generation technology to the *Spindt* type metal microtips (Fig. 8)[39, 42]. The advantages of CNTs are, above all, a potentially larger lifetime thanks to the chemical inertness, the highest current density, $10^6 - 10^{10}$ $\mathrm{Acm^{-2}}$ (over 1000 times that for copper), lower operating voltage due to higher local field enhancement and, last but not least, they can be very simply and economically manufactured [43–46]. In concrete terms, this means that the use of CNTs as electron emitter has made the production of FEDs economically feasible. More or less all big companies active in display

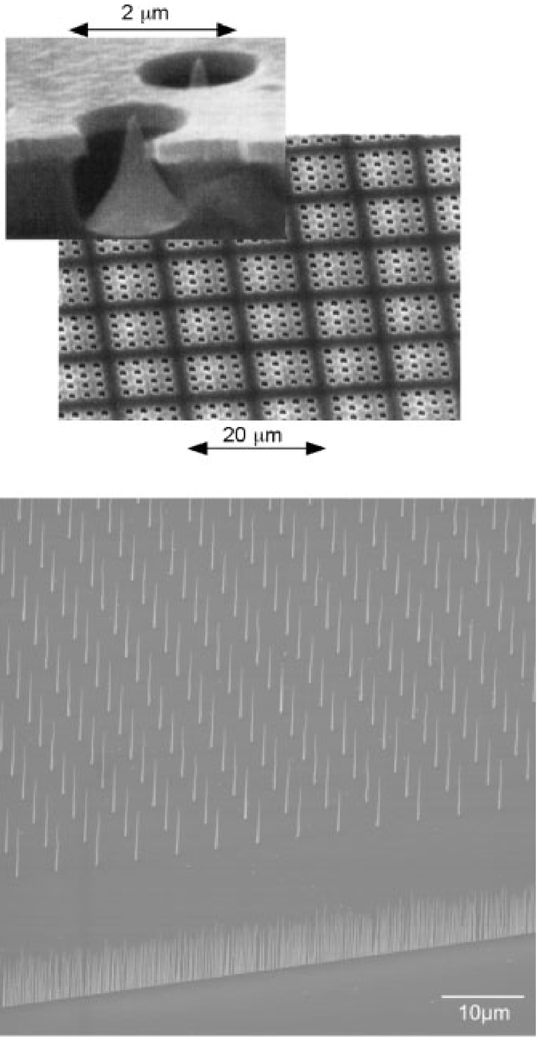

Fig. 8 (a) Field emitter array of evaporated metal tips, so called Spindt-tips[37]. (b) Array of vertical aligned CNT electron emitters grown by plasma enhanced chemical vapour deposition (PECVD (from.[39])

technology (Sony, Samsung, Toshiba, etc.) are intensively working on the development of CNT based FEDs. Prototypes have already been presented by the companies.

Quantum wells (QW) and quantum dots (QD) are further surface or interface nanostructures unknown in nature. These are nanostructures with two, respectively three dimensional carrier confinement, exhibiting strong quantised properties [47, 48]. The density of states (DOS) as well as the phonon modes vary sharply with the reduced degrees of freedom and dimensionality of the quantum system. Consequently, QWs and QDs can be designed with particular geometrical confinement and material combinations to achieve specific electronic and phonon properties. Today QWs are produced by growth on high-quality epitaxial layers of semiconductors by molecular beam epitaxy or metalorganic chemical vapour desposition. QDs, on the other hand, are mainly produced by two alternative ways: Firstly, by epitaxial growth with nano-scale patterning or surface self-assembly [47, 49, 50] and secondly, by the formation of nano-sized semiconductor particles through colloidal chemistry [51, 52]. The ability to tailor the electronic properties of materials to achieve specific optical and electronic functions by geometrical confinement was first recognised by R.D. Burnham et al. [53] and L. Esaki and R. Tsu [54] in the early 1970ies. With their pioneering works on lasing actions in hetero-structures and resonant tunnelling semiconductor superlattices to produce negative differential resistance, respectively, they opened up new horizons for a wide class of high functionality and high performance electronic and optoelectronic devices. Nowadays, through the use of advanced molecular beam epitaxy (MBE) technology, superlattice structures with almost any electronic energy levels, wave-functions and band structures can be deposited, making quantum engineering feasible. The quantum cascade laser (QCL) is an excellent example of how quantum engineering can be used to design materials with novel optoelectronic properties.

The QCL was invented in 1994 by J. Faist et al. [55] at "Bell Labs" in Murray Hill, New Jersey. The QCL is based on a fundamentally different principle to normal semiconductor lasers. It uses only one type of charge carrier, electrons, and is, therefore, called a unipolar laser. In essence the QCL operates like an electronic waterfall (Fig. 9). Passing through injectors and active transition regions repeatedly, a single electron can emit up to hundreds of photons as it travels through the corresponding number of active regions [56]. This is unlike double hetero-structure diode laser in which only one photon is emitted by electron hole recombination. Among the much higher quantum yield, the revolutionary aspect of the QCL is that it can be designed to emit any wavelength over an extremely wide range (4–24 μm), using the same combination of materials in the active region. In QCLs, the wavelength is essentially determined by quantum confinement, i.e. the layer thickness of the active region rather than by the bandgap of the material. QCLs can operate at high powers (up to 1 W in pulsed mode at room temperature) and are relative cheap to produce. All these benefits make the QCL an ideal light source in applications such as infrared spectroscopy, optical wireless communications and medical diagnostics [57].

4
Molecular Electronics and Molecular Self-assembly

Silicon-based microelectronics has advanced at exponential rates in performance and productivity throughout the past four decades. The general trend is to make devices smaller and faster and, therefore, to provide always cheaper electronic devices with greater performance for use in everyday life. It has been scaled so continuously that it is beginning to encounter fundamental limits associated with the laws of quantum mechanics, limitations of fabrication techniques, and fundamental materials properties, e.g. the breakdown voltage of ultrathin ($d < 3$ nm) gate oxides. In order to continue the miniaturization of electronic devices, entirely new nano-electronic device structures and computational paradigms are required. Although silicon will undoubtedly remain of central importance as microelectronics moves towards nanoelectronics, many would argue that carbon becomes very important in nanoelectronics too. What makes carbon so interesting for nanoelectronics? Carbon is surly the most flexible and versatile element of the periodic system. Due to the ability of its 2 s and 2 p valence electron states to form different hybrid orbitals even in the carbon-carbon bond, it can form 1-dimensional chains (sp^1 hybrid), 2-dimensional sheets with the well known graphite structure (sp^2 hybrid) and 3-dimensional networks like diamond or tetrahedral amorphous carbon (sp^3 hybrid). The properties of the different bond configurations are related to the varying number of delocalized π-electrons giving rise to conduction for the sp^1 and sp^2 hybrid case, and the very

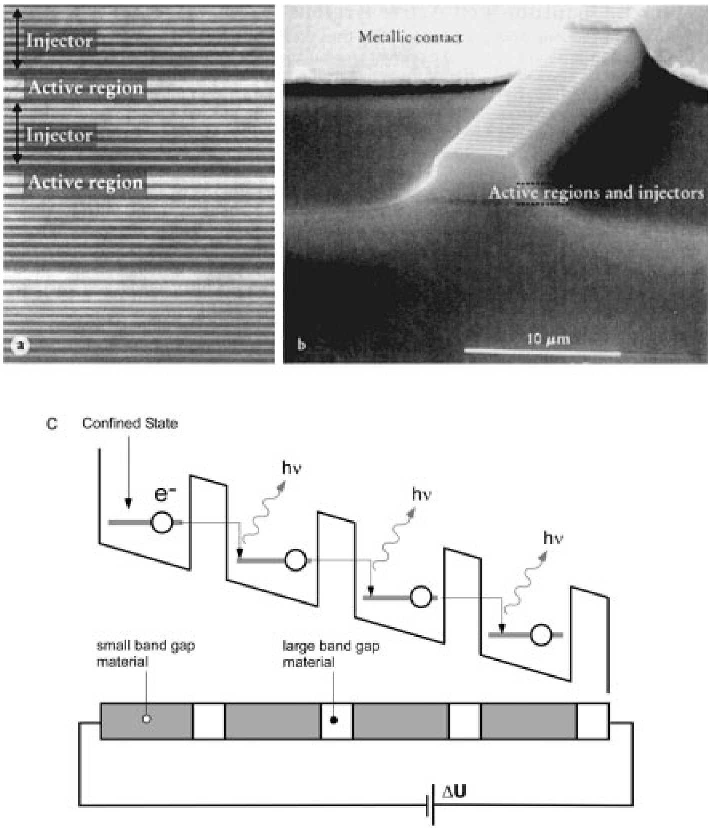

Fig. 9 (a) High resolution transmission electron microscope image showing several of the identical stages of the QCL structure, each consisting of an active region and an electron injector. The white layers in the active region are the quantum wells, made of GaInAs, separated by barrier layers (dark) made of AlInAs. The wide quantum wells in the active regions are 4.4 nm and 4.8 nm wide. (b) Scanning electron microscope image of a portion of the same QCL. The whole QCL is 8 μm wide and 2.5 mm long. (S.N. George Chu of "Agere Systems") c) Schematic energy diagram of a quantum cascade laser.

strong σ-bonds common to all hybrids leading to binding energies round 7 eV per carbon atom. Therefore, carbon materials span an enormous range of mechanical, thermodynamic and electronic properties that is larger than of any other elements. In its hexagonal sp^2-bonded graphite from, carbon is soft, semi-metallic and very anisotropic. In its four-fold-coordinated sp^3-bonded diamond form, carbon is the hardest material, the best thermal conductor and a wide band gap semiconductor with intrinsic good insulator properties. Alone on account of these two allotropic forms, carbon is a very promising material for electronic applications. But again, it was the discovery of CNTs which triggered key developments in carbon electronics.

SWNTs exhibit interesting electronic properties [58, 59]. The electronic band-structure of SWNT can be explained by the dispersion relation calculated for graphene. However, one important restriction on the allowed electronic states originates from the periodic boundary conditions in the circumferential direction of the tube. This reduces drastically the number of allowed wave-vectors in this direction and leads to the one-dimensionality of the bands, which expresses itself in the appearance of van Hove singularities in the density of states. Depending on the diameter and the chirality (Fig. 10), SWNTs can exhibit either metallic or semi-conducting electronic properties [60]. The ability to yield both metallic and semi-conducting SWNTs without

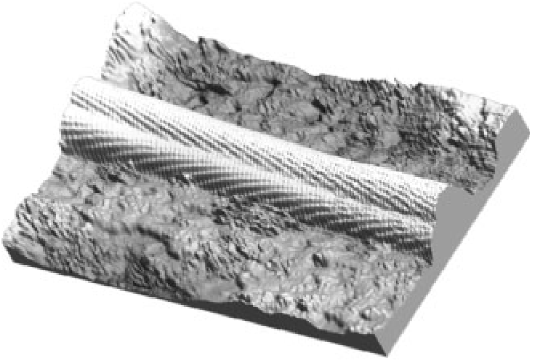

Fig. 10 Scanning Tunnelling Microscope (STM) picture of two SWNT with different chiralities. The larger tube has a diameter of $\phi = 1.2\,\text{nm}$.

doping is unique among solid-state materials and has led to the anticipation that SWNT might thus serve as a key building block for carbon based electronics.

Already in this early stage of research SWNT based field effect, transistors (FET) have shown to outperform state of the art p-Si-CMOS devices with regard to current drive and transconductance [61–64]. This clearly makes CNTs very promising candidates for electronic applications. Since CNTs are the mechanically and chemically most stable nanostructures, opportunities exist for integrating CNT electronics in other chemical, mechanical or biological systems. Examples include electrical sensing of individual biomolecules in physiological environment as well as electromechanical devices [65, 66]. Undoubtedly, CNTs are promising candidates for nanoelectronic building blocks, but the main problem to use CNT in nanoelectronics is the quality and purity of the material available. Although a great deal of work has been done, the progress to date in the controlled synthesis of CNTs has been modest. Until now there exists no synthesis route which allows the control of the chirality of the tubes. As a result, a batch of grown CNTs always contains metallic and semi-conducting tubes. Processes which allow the separation of metallic and semi-conducting tubes are slowly being developed [67, 68]. The separation of the CNTs with respect to their chirality will be an even greater challenge, and it is not at all clear whether this task can be realized at all.

A way out of this dilemma may be the use of organic molecules as electronic building blocks. Organic molecules can be relatively easily and reproducibly synthesized with extremely high purity. In addition, organic molecules can be functionalized in a great variety. This allows chemists to tailor molecules to building blocks in molecular architecture. Molecular architecture as self-assembly process is a very promising approach to create supramolecular structures with desired electronic or optical properties. As beneficial the use of molecules is with respect to tailoring properties and control purity, as enormous is the challenge in integrating specific molecules in a functional architecture e.g. adding electric contacts to molecules. Nevertheless, molecular architecture based on self-assembly processes seems a very promising approach to create supramolecular structures with desired electronic or optical properties.

A further aspect of nanotechnology is that it is not only associated with small, nanoscale objects, but also with adequate technologies to handle large numbers. As already shown, an A4 field emission display (FED) requires an array of about 10^{10} CNT electron emitters. The acceptable tolerance in length, diameter and interspacing of the CNTs for a high quality FED is in the range of 5%. This example shows clearly that nanotechnology demands drastically different approaches to manufacturing than previous technologies have taken. Instead of scaling materials down to create devices, it would be much more efficient to produce nano-sized objects by building them up piece by piece on a molecular level. The key-word of this bottom-up approach again is molecular self-assembly.

Nature is the master of self-assembly and self-organization since millions of years. Self-assembly is omnipresent in nature at both macroscopic and microscopic scales, from the assembly of flocks of birds in the sky, where the flock seems to develop behavior of its own, down to the molecular assembly of viruses or lipids. Nucleic acids, ribosomes, enzymes, proteins, etc. are molecular building blocks and molecular assemblers forming perfect biological systems by hierarchical self-assembly. The key feature here is the spontaneous organization of molecules under thermodynamic equilibrium conditions into structurally complex but well-defined and rather stable arrangements through a number of non-covalent interactions such as hydrogen bonds, ionic bonds, and van der Waals interactions (G.M. Withesides (1991)[69], J.-M. Lehn (1993)[70].) Further elements are chemical complementarity and structural compatibility. Many scientists believe that molecular self-assembly techniques will set the basis for manufacturing a wide range of objects, from electronic circuits to new materials, e.g.

advanced ceramics grown by biomineralization [72, 73]. Biomineralization is the process by which microorganisms mediate and catalyze inorganic reactions so as to form a composite assembled by minerals and organic material. An example is the mother of pearl or nacre, a remarkable robust nanocomposite despite the brittle nature of its main component aragonite (∼ 95%), the mineral of calciumcarbonate ($CaCO_3$). It is made up of about 10 µm in diameter and 500 nm thick regularly arranged aragonite platelets, held together by a 40 nm thick biopolymer glue. Although the content of the biopolymer glue is only about 5% it is dominantly responsible for the mechanical properties of nacre which has a toughness 1000 times greater than its constituents.

Since molecules are the smallest units that will ever have completely engineered electronic and optical properties, scientists have pursued the idea to build electronic circuits by molecules and molecular structures, called molecular electronics. It has been quite common in recent years to describe isolated molecular devices and their envisaged advantages [73–77], but the functional interconnection of such devices to higher levels has only rarely been achieved. One of the big challenges for molecular devices that needs to be overcome in the near future is developing strategies to build integrated circuits by bottom-up integration from the molecular scale. These molecule-based devices with advanced functions require the development of new and efficient approaches for integrating molecular building blocks into desired functional structures, ideally with these structures supported on suitable substrates. Recently, Y. Lou et al. [78] presented an evolutionary molecular design process to build up a two dimensional molecular crossbar memory device. Conventional crossbar random access memories (RAM) are made by ferroelectric and magneto-resistive materials called FeRAM and MagRAM, respectively. The electrical resistance of the crosspoints exhibits a hysteretic response to an applied field thus serving as the basis for non-volatile information storage. However, these systems also exhibit significant problems with respect to point addressability, known as "half-select" problem. The "half-select" problem arises, because in a crossbar circuits all of the devices are electrically interconnected, therefore, every junction (crosspoint) in the circuit subjected to at least some electrical fields, occasionally sufficient to alter the state of the junction since the poling process itself is based on a field driven nucleation event. This problem has seriously limited the development of crossbar RAM's. Using amphiphilic bi-stable[2]rotaxane molecules Y. Lou et al. build up a 64-bit addressable molecular switch RAM working with voltage pulses of +2 V for opening and −2 V for closing the switch. The ON/OFF current ratio was in the order of 300% which is at least one order of magnitude larger than for ferroelectric or magneto-resistive analogues. For the device fabrication, the molecules were self-assembled as Langmuir-Blodgett monolayers before being transferred to a substrate patterned with n-type polysilicon electrodes.

Supramolecular aggregation – or self-assembly – occurs spontaneously and can lead to controlled structures if selective and directional non-covalent interactions are exploited. It occurs in liquids as well as at surfaces and interfaces. In view of future molecular electronics self-assembly on solid surfaces is particularly important. A beautiful demonstration of this approach has recently been given by T. Yokoyame and co-workers [79] who have shown the formation of surface-supported supramolecular structures whose size and aggregation pattern are rationally controlled by tuning the non-covalent interactions between the individual adsorbed molecules. They demonstrated that structures formed by substituted porphyrins adsorbed on a gold surface correspond in a predictable fashion to the geometrical and chemical nature of the substituents that mediate the interactions between the adsorbed molecules. These findings suggest that careful positioning of functional groups that are able to participate in directed non-covalent interactions, will allow the rational design and construction of a wide range of molecular architectures adsorbed on surfaces. A first proof of principle of this approach has recently been given by. J. A. Theobald et al. [80] with the self-assembled growth of perfectly regular supramolecular hexagonal networks from perylene tetra-carboxylic di-imide (PTCDI) and melamine molecules on a Ag/Si(111) surface (Fig. 11).

Recently, R. Fasel et al. [81, 82] have demonstrated the transfer of chirality from single helical molecules into self-assembled monolayers. Although the self-organisation of chiral molecules into helical architectures is of fundamental importance in nature and has found important applications such as liquid crystal technologies [83], the mechanism of chirality induction is still poorly understood. By means of STM Fasel et al. have shown that helical heptahelicane molecules ([7]H, $C_{30}H_{18}$) absorbed into the close-packed monomolecular layer forms on Cu(111) handed supramolecular structures (Fig. 12). They demonstrated that

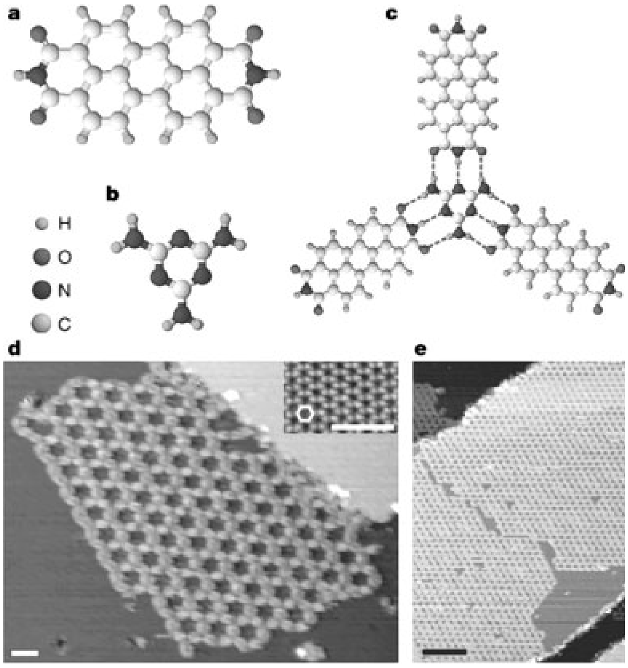

Fig. 11 Self-assembly of a PTCDI-melamine supramolecular network. Chemical structure of PTCDI (a) and melamine (b). c), Schematic diagram of a PTCDI-melamine junction. d) STM image of a PTCDI-melamine network. Scale bars, 3 nm. e) STM image of large-area network, with domains extending across terraces on the Ag/Si surface.[80] Scale bar, 20 nm. (from [80])

the self-assembly of molecules on surfaces is not only governed by the lateral molecule-molecule, but is also influenced by the molecule-substrate interaction, which, in turn, determines the mobility of the molecular species at the surface at a given temperature. They found, that the chirality transfer from the molecule to the self-assembled monolayer occurs through steric repulsion and does not require molecular flexibility or strong dipole interactions. The appearance of handed molecular clusters is due to a correlation of azimuthal molecular orientations which are driven by repulsive intermolecular forces in the close-packed 2D layer.

Molecular self-assembly is of course the most promising bottom-up concept in nanotechnology. Precisely controlled molecular self-assembly, as shown by the few examples above, has the potential to be a whole new engineering paradigm, much like engineering semiconductors.

(b) (P)-[7]H at θ = 0.95. c) (M)-[7]H at θ = 1.0. d) (P)-[7]H at θ = 1.0. The (M)- and (P)-[7]H structures are mirror images of each other.(from [81])

5
Outlook

Whereas science aims at the advancement of our knowledge in the physical world and its phenomena, technology aims at the application of knowledge to improve our environment and life quality. It is natural that science and technology are linked by knowledge and that science usually precedes technology. We see today that in industry the awareness of processes and engineering at the nanometer level rapidly increases and products using materials engineered at the nanometer level emerge on the markets. In that sense we believe that it is absolutely justified to talk of nanotechnology as opposed to pure nanoscience. It may also be true that in many cases nanotechnology is not "visible" in the final product any more, as e.g. in an anti-scratch lacquer or an anti-reflection coating on viewing glasses, where nanotechnology might be much less related to radically new "nanoproducts" – but enabling new functionalities to well established products and new ways of producing them. In the long term, it is hardly possible to estimate, from the present point, where the ability to engineer materials on the nanoscale will lead us, whether the dream of a molecular nanotechnology with autonomous working machines built with atomic precision will ever become reality. Again nature might give us some hints, as it has realized such machines in the form of proteins working in our bodies all the time.

History teaches us, that in long term forecast future revolutionary technologies were always underestimated. Thus, experts believed, having invented the transistor in 1948, that one day, it might be possible to build a computer by semiconductors with 5000 operations per second weighing 1500 kg only, consuming 10 kilowatt. Today's PCs are in all respect 100'000 more powerful. Similarly it was with the electricity at the end of the nineteenth century or with telecommunication at the end of the twentieth century. Future will show whether nanotechnology will be placed in this line of revolutionary technologies.

Separation Techniques for Carbon Nanotubes

Ralph Krupke and Frank Hennrich

1
Introduction

The microelectronic revolution has been driven by the exponential enhancement of computer power over several decades, a development that had been predicted in 1965 and is known as Moore's law [1]. The progress has been enabled by lithography, a top to bottom process which allows to produce a deterministic network of transistors and wires. Advancements in lithography towards smaller feature size are ongoing, however within the next 10 to 15 years lithography might reach physical limits preventing further miniaturisation [2]. Moreover the exponentially growing lithography cost (second Moore's law) probably leads to a deviation from the actual rate of feature size shrinkage before the year 2015 [3].

A perspective towards smaller or cheaper circuitry might arise from molecular nanostructures. The developing field of nanoelectronics or molecular electronics explores the potential of organic molecules or inorganic clusters to be used as building blocks. In particular single-walled carbon nanotubes as quasi 1-dimensional molecular nanostructures have been identified as promising candidates for nanoscale transistors or nanoscale wires [4]. Yet, for applying carbon nanotubes in a future nanocircuitry, there exist several problems to be solved such as the mixed growth of metallic and semiconducting carbon nanotubes, the assembling of carbon nanotubes into functional structures or controlling the interface between a nanotube and the microscopic world. The purpose of this article is to report on recent progress on one of the grand challenges, the separation of metallic from semiconducting single-walled carbon nanotubes and to give an overview over this new emerging field.

A single-walled carbon nanotube (SWNT) can be thought of a graphene sheet seamlessly rolled up to a hollow tube with a one atomic layer wall of hexagonally arranged carbon atoms (Fig. 1). By varying the dimensions of the sheet and changing the pitch of the rolled up sheet, tubes with variations in diameter, length and chiral angle can be imagined. Apart from its length, a SWNT is defined by its roll-up or chiral vector (n,m) based on the unit vectors of the carbon atom lattice. It is remarkable that SWNTs, although composed purely out of carbon, may behave either as metals or as semiconductors just due to minute differences in the geometry. Quantum size effects determine that tubes with $n = m$ are metallic or quasi-metallic (with a tiny band-gap) if $n - m$ is divisible by 3. All others tubes are semiconducting with band gaps of the order of 0.5 eV.

Concerning nanoelectronic applications, metallic SWNTs (M-SWNT) are exceptional nanoscale leads with ballistic electron transport over several μm and current densities up to $10^9\,\mathrm{A/m^2}$. Semiconducting SWNTs (S-SWNT) can be wired up to function as fast nanoscale transistors or sensitive nanoscale sensors. For most electronic applications a preferential growth of only metallic or only semiconducting SWNTs would be highly desirable. Indeed Li and co-workers have concluded from their data that the ratio of metallic to semiconducting tubes depends on the production method, which might indicate that chirality controlled growth could be achieved in the future [5]. However in practice SWNTs are grown as mixtures of the two tube types, which makes separation schemes inevitable.

2
Separation Techniques

A pre-condition for efficient separation is that tubes are individualized within mixtures of metallic and semiconducting tubes, meaning that they do not form bundles as generally observed. This can be achieved by suspending SWNTs in aqueous surfactant solution under sonication, where many bundles split up and the individualized tubes then being hindered by the surfactant to rebundle. Remaining bundles can be removed by ultracentrifugation [6]. The scheme of O'Connell and co-workers is now used by other groups as well achieving with various surfactants such as sodium benzene sulfonate similar results. The fingerprints of a surfactant stabilized individual SWNT suspension are sharp absorption peaks in the optical absorption spectra in contrast to broad bands for suspended bundles. Furthermore surfactant stabilized SWNT suspensions show fluorescence in the near infrared region, emitted by semiconducting tubes which otherwise is quenched by the nearby metallic tubes in bundles. It should be noted that the observation of sharp absorption peaks and fluorescence indicates a rather large

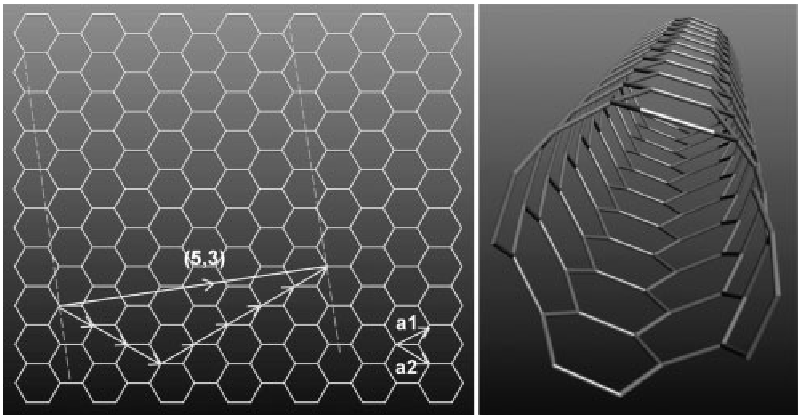

Fig. 1 A single-walled carbon nanotube is determined by its chiral vector (*n,m*) based on the unit vectors a1 and a2 of the graphene lattice, where one carbon atom is sitting at each corner of the lattice. As an example, a (5,3) SWNT (right panel) is formed by cutting a strip of a graphene sheet along the dashed lines (left panel) and rolling it up, such that the starting and the end point of the chiral vector fall on each other.

fraction of individualized SWNTs in the suspension but it is not sensitive to exclude the presence of a small fraction of bundles, an information which can be given by atomic force microscopy or transmission electron microscopy after transferring tubes onto a surface.

Before describing the separation techniques we emphasize that the analysis of supposedly separated material is not trivial. Electron transport measurements can be used on the level of a single tube to determine whether a tube is a M-SWNT or a S-SWNT and by doing so on many tubes, a statistical access to the ratio of M-SWNT to S-SWNT is given. In principle one could also determine for a single tube the (n,m) directly from STM and TEM measurements with atomic resolution. But although these measurements would give exact numbers of the M-SWNT and S-SWNT ratio, they are too time consuming as to be used for routine measurements. For those reasons most of the reviewed work is analysed by either optical absorption or resonant Raman spectroscopy. Since optical absorption cross-sections or Raman cross-sections are likely to be (n,m) dependent and are not known or under debate, both measurements do not provide absolute values for the M-SWNT and S-SWNT ratio at the moment. However the relative enrichment in M-SWNT or S-SWNT can be determined.

Optical absorption spectra can be taken either on suspended tubes or on thin films. In general absorption peaks or bands are observed in three regions of the UV-VIS-NIR spectra. Spectral features within two regions at low energy are associated with excitations of S-SWNTs (S1, S2) and an additional region at high energy coming from excitations of M-SWNTs (M1) (Fig. 2). The energetic positions of the regions depend on the mean diameter of the SWNTs. A ratio S1/M1 or S2/M2 can be obtained by dividing the integrated intensities of the peaks or the band of the regions respectively. When compared with a reference sample it allows to derive the degree of enrichment or even to calculate the sample composition, if the composition of the original reference sample is assumed to have the theoretically expected value of 2/1.

Raman spectroscopy on SWNTs has turned out to be an analysis tool which allows to characterize rather small quantities of material down to a single SWNT. In contrast to optical absorption not all tubes contribute to the spectra but only those which are resonantly excited (Fig. 2). Important features for analysing the spectra are the radial breathing modes (RBM) and the tangential modes (G-modes) of carbon atoms oscillating out of or in parallel to the nanotube surface, respectively. Although details of the spectra and their origin are still under discussion it is now widely accepted that the shape of the G-mode is significantly different for M-SWNT and S-SWNT. Furthermore, depending on the diameter distribution of the sample and the laser wavelength used, M-SWNT and S-SWNT with different diameter are excited, which splits the RBM range into regions associated with M-SWNT and S-SWNT. Estimate of the enrichment of

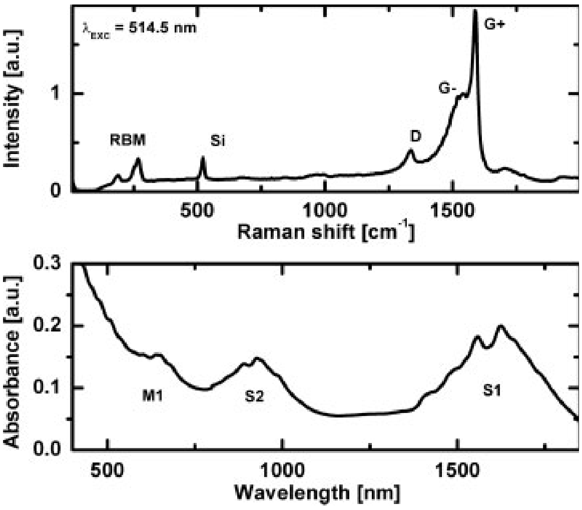

Fig. 2 Typical Raman- (top) and UV-VIS-NIR spectra (bottom) used for analysing the degree of separation or enrichment in metallic or semiconducting SWNTs.
Bottom: S1 and S2 denote the first and second excitation energies of semiconducting SWNTs, respectively. Due to inverse scaling of the excitation energy with the diameter, the position and the width of S1 and S2 depends on the mean diameter and diameter distribution of SWNTs in the sample. M1 denotes the first excitation energies of metallic SWNTs. The steep increase of absorbance below 500 nm is due to higher order excitations and the pi-plasmon. The sharp wiggles are only observed for samples with a large content of unbundled tubes.
Top: SWNTs which are resonantly excited contribute to Raman spectra comprising of radial breathing modes (RBM), the disorder mode (D) and the tangential modes (G+ and G−). In this particular example, two regions of RBMs are observed, coming from the simultaneous excitation of a few metallic and semiconducting SWNTs with different diameter. Also observed is a sharp and intense G^{+}-mode, typical for semiconducting SWNTs, and a broad G^{+}-mode, typical for metallic SWNTs (see also Fig. 4).

a sample is then done in a similar fashion as for the optical absorption measurement by calculating the ratio of the integrated peak intensities of RBM bands originating from M-SWNT and S-SWNT and comparing it with a reference sample. Furthermore variations in the shape of the G-mode for the two tube types can be used for analysis. Of course for optical absorption and Raman spectroscopy it is important to compare samples of similar morphology. For instance spectral changes can be observed upon bundling which are not related to compositional changes.

In the following separation techniques are promoted which, as a starting material, use individual SWNT suspensions with the above discussed optical properties. Then techniques are described which are using suspensions of bundled SWNTs and finally alternative concepts are presented.

2.1
Separation via Dielectrophoresis

Separating metallic from semiconducting SWNTs, starting from individual tube suspensions, was first obtained via alternating current dielectrophoresis [7]. The physical method makes use of the different polarisabilities of M-SWNT and S-SWNT induced by an electrical field. Theoretically it was expected that the dielectric constant of S-SWNT is of the order of $5{\cdot}\varepsilon_0$ compared to $80{\cdot}\varepsilon_0$ for aqueous surfactant solution. For M-SWNT the dielectric constant should be at least of the order of $1000{\cdot}\varepsilon_0$. The dielectric constants of S-SWNT and M-SWNT being smaller and larger than that of water gives access to separate the two tube types by exposing them to a strong and inhomogeneous electrical field. The interaction of the induced dipole moment with the inhomogeneous external field leads to a movement of the M-SWNT towards the high field region whereas the S-SWNT move into the opposite direction towards the low field region (Fig. 3).

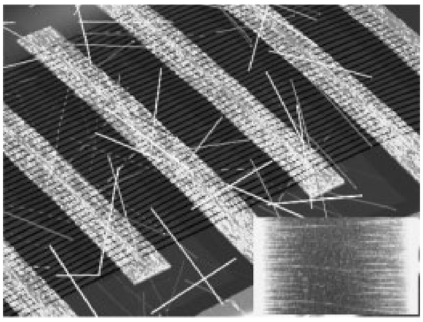

Fig. 3 Illustrated dielectrophoretic separation of metallic from semiconducting SWNTs. Planar microelectrodes, powered by an ac-voltage generator, impose a strong dielectrophoretic force on SWNTs suspended in aqueous solution. The highly polarizable metallic SWNTs (black) are dragged to the electrodes whereas the less polarizable semiconducting SWNTs (white) remain in suspension. The separation is observed for a nominal electrical field of 10^6 V/m and electric field frequencies above 3 MHz[17]. The inset shows an optical microscopy image of aligned metallic SWNTs forming bundles and ropes, eventually bridgeing the electrode gap.

This dielectrophoretic response is competing with the electrophoretic response which is due to the interaction of the field with charges sitting on the tubes when suspended in aqueous solution. This static charge accumulation does not only depend on the intrinsic electronic properties but also on the diameter and length and therefore is not an appropriate property to be used for separating M-SWNT from S-SWNT. To avoid an electrophoretic response an alternating electrical field of a few MHz has been used, where the oscillatory electrophoretic movement in the ac field results in a zero displacement of the tubes. In contrast the dielectrophoretic response leads to a net opposite movement of the two tube types since their induced dipole moment is always in phase with the ac field even at the highest frequency used in the experiment.

The experimental setup comprises of a planar interdigitated microelectrode array with electrode gaps of typically 20 μm which is powered by an ac power generator with a sinoidal waveform and a peak to peak voltage of typically 20 V. The setup produces a strong and inhomogeneous ac electrical field with a nominal field strength of the order of 10^6 V/m. Applying a drop of individual SWNT suspension onto the array leads within minutes to the deposition of metallic SWNTs forming bundles at the surface, which are growing along the field lines and eventually connect the opposing electrodes. The deposited material has been analyzed by resonant raman spectroscopy and showed that primarily M-SWNT had been deposited. In the original work it had been estimated that 80% of the deposited material are M-SWNT. By further reducing the residual bundle content in the starting suspension, a complete separation has been achieved in the sense that by Raman spectroscopy no S-SWNT can be detected in the dielectrophoretic samples (Fig. 4).

It should be noted, that in a similar experiment, albeit with bundled material, Lee and co-workers have found that S-SWNTs are strongly enriched in the leftover suspension, as expected [8].

In the proof-of-principle experiment about 1 ng of tubes can be separated from a 10 μl drop of tube suspension per run. For the technique to become an industrial technology at least 6 orders of magnitude in separation capacity have to be gained. To achieve this goal the technique has to be scaled up. A problem is that the dielectrophoretic force reduces within the first 10 μm above the electrodes by two orders of magnitude leaving most of the tubes in the drop unexposed to sufficiently strong dielectrophoretic forces. However, a microfluidic setup with the electrode array being embedded in a shallow channel would allow to expose the suspension to sufficiently strong dielectrophoretic forces.

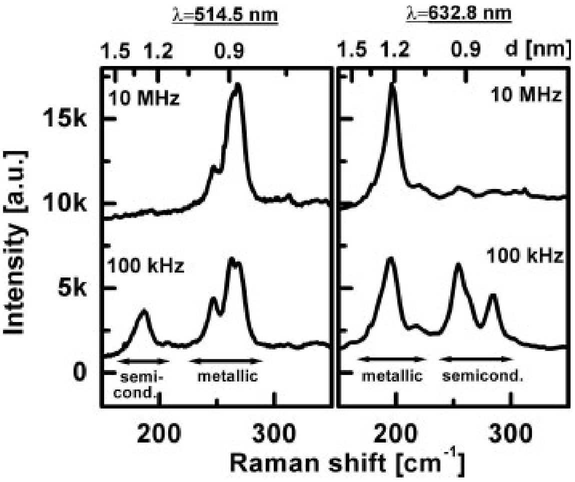

Fig. 4 Comparison of SWNTs deposited with ac-dielectrophoresis at different field frequencies (10 MHz and 100 kHz) by analyzing the Raman signal in the Radial Breathing Mode region with two laser excitation wavelengths λ = 514.5 nm and λ = 632.8 nm (left and right panel, respectively). At 514.5 nm small metallic SWNT with d $\approx$ 0.9 nm and large semiconducting SWNTs with d $\approx$ 1.2 nm are excited[7]. At 632.8 nm large metallic SWNTs with d $\approx$ 1.2 nm and small semiconducting SWNTs with d $\approx$ 0.9 nm are probed. The data demonstrates, that separation of metallic from semiconducting SWNTs is obtained for high frequency ac-dielectrophoresis at 10 MHz, independent from the tube diameter.

2.2
Chemical Selectivity to Metallic Tubes

More easily scalable would be a chemical access to separate M-SWNT from S-SWNT. Indeed M. Strano and co-workers reported that diazonium reagents, under carefully controlled conditions, primarily reacts with M-SWNT [9]. Also here the starting materials were surfactant stabilized individual SWNT suspensions. Confirmation of the selective reaction is given by optical absorption spectroscopy where mainly the absorption peaks associated with M-SWNT initially decay under addition of the diazonium reagents. Further confirmation is given by the evolution of the Raman spectra with increasing diazonium agent concentration, which shows that small M-SWNT are the most reactive species.

The model used to explain the selective reactivity describes the diazonium agent extracting electrons, thereby evolving N_2 gas and leaving a stable C-C covalent bond with the nanotube surface. It is assumed that the availability of electrons near the Fermi level stabilizes a charge-transfer state that is preceding the bond formation, which finally leads to a higher initial reactivity towards M-SWNT. However the reactivity is also anticipated to depend on the chiral angle, chemical doping and charged adsorbates.

Having found a chemistry which appears to be selective towards primarily M-SWNT it is now the challenge to extract the M-SWNT from the still mixed suspension. In that sense the M-SWNT are not yet separated from the S-MWNT but have been modified chemically such, that they are no more detectable by optical spectroscopy.

A selective electrochemical modifications of those M-SWNTs, which have been wired to electrodes on a surface, has been achieved by Balasubramanian and co-workers [10]. The authors used similar to Strano et al. a diazonium agent to functionalize M-SWNT. However in this experiment the reaction was driven by an electrical potential applied between electrodes in touch with tubes and a counter electrode. The authors found conditions in which primarily M-SWNTs did react, once the S-SWNTs were driven into the non-conducting state by an appropriate gate voltage. Experimental verification of the selective modification is given by transport measurements in which the signatures of M-SWNTs disappear after the treatment.

2.3
Selection via Ion Exchange Chromatography

Another chemical approach is to separate SWNTs by anion exchange chromatography. M. Zheng and co-workers have found out that single-stranded DNA interacts strongly with SWNT to form a stable DNA-SWNT hybrid that effectively disperses SWNTs in aqueous solution under sonication [11]. Such DNA-SWNT suspensions do show similar sharp optical absorption peaks and fluorescence as surfactant stabilized individual tube suspensions. Since the phosphate groups on a DNA-SWNT hybrid provide a negative charge density on the surface of a nanotube, the authors anticipated that a DNA-(M-SWNT) has less surface charge than DNA-(S-SWNT) due to screening of the charge by the M-SWNT. To take advantage of the difference for SWNT separation, an ion-exchange liquid chromatography experiment was performed, where the difference in surface charge should modify the interaction of the hybrid with the resin and hence the propagation speed through the column. Experimentally, the chromatogram (the evolution of the absorbance with time) shows two bands due to free DNA (first band) and DNA-SWNT (second band). In the initial experiment two fractions of the DNA-SWNTs bands were analysed, indicating by optical absorption measurements an enrichment of M-SWNT in the early fraction. In addition length variations of the two fractions were analyzed by atomic force microscopy, indicating that SWNTs in the earlier fraction are shorter. Hence the conclusion was that M-SWNT and S-SWNT separation is convoluted by the tube length variations.

More recently the authors conducted a systematic study whether the formation of the DNA-SWNT hybrid is sequence dependent [12]. The result was that DNA sequences rich in guanine and thymidine amino acids are particularly useful for the formation of stable aqueous suspensions. These suspensions were then split up into various fractions by the anion exchange liquid chromatography. Optical absorption spectra again revealed an enrichment in M-SWNT in the early fractions but now convoluted with a variation in diameter. SWNTs with a smaller diameter pass the column faster than SWNTs with a larger diameter. Recently M. Strano with M. Zheng and co-workers performed an extensive analysis on the very same samples by combined fluorescence and raman spectroscopy [13]. The result is that the separation of the suspensions by anion exchange liquid chromatography is primarily according to the diameter of the SWNTs, independent of the metallic or semiconducting nature of the SWNTs. The results are certainly complex, but definitely show that ion exchange chromatography allows to separate DNA-SWNT hybrids at least according to their diameter.

2.4
Selective Destabilisation of Tube Suspensions

We now come to separation techniques which use suspensions of bundled SWNT as starting material. It is obvious that separation can not be achieved if bundles are of heterogeneous composition, however for small bundles some degree of enrichment is possible. For instance Chattopadhyay and co-workers reported an enhanced solubility of S-SWNT when dispersed with octadecylamine (ODA) in tetrahydrofuran (THF) [14]. The authors assume that ODA physisorbs along the SWNT sidewalls, with the amino group having a stronger affinity to S-SWNT than to M-SWNT, and thereby providing additional stability to the physisorbed ODA. In contrast M-SWNTs were more likely to precipitate.

In the experiment ODA stabilized SWNT suspensions were prepared in THF with bundles containing between 2-6 SWNTs. Over a period of a few weeks sedimentation of parts of the ODA-dispersed SWNTs takes place, which can be accelerated to minutes by solvent evaporation. Analysis of the sediment by Raman spectroscopy indicates an enrichment in M-SWNT as compared to the supernatant.

Recent quantitative analysis of the Raman spectra on such samples by G. Samsonidze and co-workers revealed that the separation efficiency is convoluted by variations in the tube diameter [15]. In particular poor enrichment is observed for larger-diameter tubes, which becomes more efficient towards smaller tube diameter. The origin of this diameter dependence on the enrichment is not yet understood but the authors point onto electronic amine-SWNT interactions or curvature-induced stabilization.

In another work, Z. Chen and co-workers have added dropwise diluted bromine to Triton X-100 suspended SWNT and SWNT bundles, and observe a sedimentation of tube material enriched in M-SWNT [16]. No enrichment is observed for experiments using sodium dodecyl sulfonate as the surfactant. The authors take this as evidence that the enrichment mechanism involves bromine induced destabilization of the Triton X-100 surfactant shell, with greater specificity for the M-SWNT. The enrichment is shown by comparison of optical absorption spectra of films from bromine treated supernatant and sediment after thermal removal of the bromine.

3
Summary

It remains a challenge for separation methods to produce substantial quantities of suspensions containing only metallic SWNTs or only semiconducting SWNTs of pristine quality for applications. Certainly a chemical access to separation appears to be promising, since a chemical recipe should be easily scalable. However up to now a spatial separation of metallic SWNTs from semiconducting SWNTs by chemical means has not been obtained. Either metallic SWNTs have been selectively functionalized but still being in the treated sample and hence not spatially separated from the semiconducting SWNTs. Or fractions enriched with metallic or semiconducting SWNTs have been obtained, however with the degree of enrichment being diameter dependent. Also the dielectrophoretic separation, a physical method, exhibits a diameter dependence if performed at low electric field strength, and only enriches M-SWNTs if processed at low frequency [17]. However for sufficient high field strength and field frequency a spatial separation of metallic SWNTs from semiconducting SWNTs is observed, independent from the diameter (Fig. 4). Under these separation conditions only the different intrinsic polarisabilities of the two tube types matter.

It might well be that upon further improvement not one particular method will prevail but rather a smart combination of methods, adjusted to specific applications. Certainly it remains exciting to see what new methods will be discovered in this emerging field of nanotube separation. In this context we refer to recent progress in electronic type selective separation of nanotubes by density gradient centrifugation [18], chemical treatment [19, 20], and dielectrophoresis [21].

Glossary

Single-walled carbon nanotube A single-walled carbon nanotube is a single sheet of graphite (graphene) rolled-up to a seamless cylinder. Its electronic property depends on the diameter and chirality due to quantum confinement of the electron wave function around the nanotube circumference. So far the electronic properties of nanotubes have not been controlled during growth.

Raman spectroscopy Raman spectroscopy is a spectroscopic technique used to study vibrational, rotational, and other low-frequency modes in a system. It relies on inelastic scattering, or Raman scattering of monochromatic light, usually from a laser in the visible, near infrared, or near ultraviolet range. The laser light interacts with phonons or other excitations in the system, resulting in the energy of the laser photons being shifted up or down. The shift in energy gives information about the phonon modes in the system. In single-walled carbon nanotubes the Raman spectra are resonantly enhanced due to singularities in the electronic density of states.

Dielectrophoresis Dielectrophoresis is the translational motion of a polarisable object in an inhomogenous electric field. Dielectrophoretic forces are usually much weaker than electrophoretic forces, which depend on the net charge of the object interacting with the electric field. Electrophoretic motion is suppressed in alternating current electric fields where dielectrophoresis can still be observed.

Ion exchange chromatography Ion-exchange chromatography is a process that allows the separation of dissolved ions and polar molecules based on their charge properties. Dissolved molecules (analyte) are driven with a mobile phase (solvent) through a stationary phase (resin) where retention times depend on the interaction between the analyte and the stationary phase.

Density gradient centrifugation A method of separating macromolecules by their differential rate of sedimentation in a centrifugal gradient and by their differential bouyancy in a density gradient. At equilibrium each particle settles in the gradient at a point equal to its density.

Ceramic Materials for Advanced Solid Oxide Fuel Cells

Peter Holtappels, Ulrich Vogt and Thomas Graule

1
Introduction

Although the SOFC has been known since 1911 and a first concept for large scale stationary SOFC systems was presented in 1937 by Baur and Preis [1], the first significant worldwide development wave did not start until the 1960 s when the Batelle Institutes in Switzerland (Geneva) and Germany (Frankfurt) began developing the technology. A detailed historical overview is given by Möbius [2].

The status of particular SOFC materials and cell development up to 1993 has been described in detail by Minh [3] and Hammou [4]. Of these early developments, only the tubular concept developed at Westinghouse (now Siemens-Westinghouse) has been pursued up to the present day. During the 1980s, advances in ceramics processing led to flat plate (planar) cell concepts, which compared to the Siemens-Westinghouse cells offer higher volumetric power densities.

SOFC development today covers cells and systems for stationary combined heat and power (CHP) production from 1 $\mathrm{kW_{electric}}$ for single-household applications to 200 $\mathrm{kW_{electric}}$ for decentralised and industrial CHP applications. Sulzer HEXIS [5] and Siemens-Westinghouse are two of the leading developers of stationary systems in Europe and the US, respectively. Japan also has considerable programmes devoted to stationary SOFCs [6]. Towards the end of the 1990s, BMW announced the development of SOFC systems to replace the alternator in cars, and this promoted increasing interest in SOFC systems for automotive applications worldwide. For detailed information the reader is referred to the most recent reviews [7, 8].

Current developments in SOFCs concentrate mainly on increasing the durability and lowering the cost of the system and the materials therein. A way to reach these goals is to decrease the operating temperature without incurring performance losses rather than further increasing the performance of the cell.

The scope of this contribution is to provide a general overview and selected examples of the most recent trends in materials development for advanced solid oxide fuel cells operating at temperatures around 800 °C.

2
Fundamentals of Solid Oxide Fuel Cells

The operating principle of an SOFC is shown in Figure 1. The conversion of chemical into electrical energy is achieved by separating a chemical reaction into two electrochemical reactions taking place inside the two porous electrodes. At the fuel electrode (anode), hydrogen and carbon monoxide are oxidised with oxygen ions from the electrolyte to form water and carbon dioxide, respectively. The resulting electrons are transported through an external circuit to the air electrode (cathode) where they are used to reduce oxygen to oxygen ions, which are subsequently transported through the electrolyte to the fuel electrode.

The fuel and air atmospheres have different electrochemical potentials related to the difference in the oxygen partial pressures in the fuel and air compartments. The resulting potential difference across the cell is the so-called Nernst potential. A typical fuel gas mixture corresponding to partially-oxidised methane (natural gas) contains 0.23 bar hydrogen, 0.2 bar carbon monoxide, 0.03 bar water and 0.06 bar carbon dioxide, with nitrogen forming the balance to 1 bar. The resulting oxygen partial pressure is 10^{-20} bar at 850 °C. The difference against the air compartment (0.21 bar oxygen) leads to a voltage across an unloaded cell of 1.02 V.

During operation of the fuel cell (external electrical circuit closed), a current can be generated which is proportional to the electrochemical conversion rate of hydrogen and carbon monoxide to water and carbon dioxide, respectively. However, the electrode reactions and the oxygen ion transport through the electrolyte lead to losses that reduce the cell voltage with increasing current flow. In order to achieve high electrical power ($P = \mathcal{U} \cdot i$), the losses in both the electrodes (the so-called anodic ($\ddot{\eta}_\mathrm{a}$) and cathodic ($\ddot{\eta}_\mathrm{c}$) overpotentials, see Fig. 1) and the ohmic losses in the electrolyte layer ($i\,R_{\ddot{\alpha}1}$x Fig. 1) should be minimised. Therefore, highly electrochemically-active electrode materials and fast oxide ion-conducting materials are required for use as electrodes and the electrolyte, respectively.

The cell components, along with their function, specific requirements and the typical materials used to manufacture them are summarised in Table 1.

The solid oxide fuel cell can be regarded as a laminated structure of three different functional materials. The cell, therefore, is an all-solid-state system for which different designs may be realised. An overview of the various cell designs can be found in earlier reviews [4, 7, 8].

Both tubular and flat plate cells with either the electrolyte, or an electrode, forming the mechanically-supporting part of the cell have been developed up to a high level of performance. Reducing the electrolyte thickness by using supported electrolyte layers (e.g. by having the anode as the electrolyte-bearing component, as shown in Fig. 2) permits the ohmic losses in the electrolyte layer to be reduced and makes lower operating temperatures around 700–850 °C feasible. At operating temperatures below 850 °C, ferritic steels can be used as interconnect materials, and this significantly reduces the cell material costs.

Several concepts and designs for supported thin electrolyte cells have been pursued, with the anode-supported electrolyte cells having attracted particular interest during recent years.

After the Forschungszentrum Jülich demonstrated the feasibility of the anode-supported electrolyte design [9], most SOFC developers worldwide started their own development line of anode-supported electrolyte cells. Great progress has been made to improve the performance of this cell type, with state-of-the-art cells reaching up to 1 W/cm^2 at 750–850 °C (0.5 W/cm^2 at 0.7 V) in hydrogen fuels [10]. Stacks up to 10 kW have been successfully tested with hydrogen and with pre-reformed natural gas.

Today, most R&D activities worldwide are concentrating on a flat plate planar cell design with the fuel electrode (anode) as the cell-supporting component. This concept combines a high volumetric power density with the capability to operate at reduced temperatures around 800 °C. In this contribution we will focus on the main

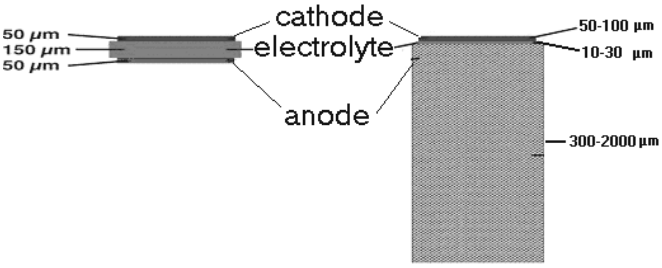

Fig. 2 Comparison of self-supported electrolyte cells (left) and anode-supported electrolyte cells (right) in the flat plate design.

development paths for materials and cell fabrication of advanced supported electrolyte cells which feature such reduced operating temperatures.

3
Materials for Advanced Solid Oxide Fuel Cells

3.1
Anode

At the anode, the fuel is oxidised in the presence of oxygen ions from the electrolyte according to Eq. 1.

$$\mathrm{Re}d_g + n\ O_O^x = Ox + n\ V_O^{\cdot\cdot} + 2n\ e^- \quad (1)$$

Equation 1 is written in the so-called Kröger-Vinck notation, where the subscript indicates the site in the ionic lattice and the superscript the electrical defect compared to the regular lattice. Accordingly, $O^x{}_O$ denotes an oxygen ion (oxidation state-II) on an oxygen site in the oxide electrolyte lattice, and $V_{O^{\cdot\cdot}}$ indicates a vacant oxygen site in the electrolyte lattice (representing a double positive charge in comparison to an occupied site). *Red* and *Ox* refer to the reduced and oxidised fuel species, respectively, and the subscript *g* refers to the gas phase (see Table 2). 2 *n* denotes the number of electrons involved in the electrochemical reaction.

Under reducing atmospheres in the fuel electrode, metals are stable over a wide range of operating conditions. For SOFCs operating at temperatures between 900 °C and 1000 °C, several materials and alloys have been investigated, and Ni has become the material of choice due to its high electrochemical activity for the hydrogen oxidation reaction, acceptable cost, and suitable chemical compatibility. In order to adjust the coefficient of thermal expansion (CTE) of a Ni-containing anode to that of the electrolyte (yttrium stabilised zirconia, YSZ), Ni powder is mixed with the electrolyte material to form a ceramic-metal composite, the so-called Ni-YSZ cermet. In the Ni-YSZ cermet, the ceramic forms a matrix which prevents the Ni powder from agglomerating and thus maintains the porous and highly dispersed microstructure of the anode. At Ni contents of around 40 vol%, the cermets are electronic conductors (500–1800 S/cm) and exhibit a thermal expansion coefficient close to that of the pure electrolyte material YSZ.

Up to now, Ni-YSZ cermets have been the state-of-the art anode material providing high performance hydrogen oxidation even at temperatures of 800 °C [11]. A measure for the electrochemical activity is the

area specific resistance, R_{as}, which reflects the energetic losses arising from the electrochemical processes in the electrode. The area specific resistance is usually expressed in $\ddot{\alpha}$ cm^2. The electrochemical activity of Ni-YSZ electrodes is such that the area specific resistance reaches values of ≈ 0.15 $\ddot{\alpha}$ cm^2 at 850 °C and <0.1 $\ddot{\alpha}$ cm^2 in the range 950–1000 °C.

The hydrogen oxidation reaction in Ni-YSZ cermet electrodes has been investigated for both technical electrodes and model systems. The results reveal that the reaction is limited by the length of the so called triple-phase boundary (TPB) region [12, 13], where the electronic conductor Ni, the oxygen ion conductor YSZ and the gas phase are in contact with each other. Possible steps in the hydrogen oxidation reaction in the vicinity of the TPB-line are adsorption, surface diffusion, and charge transfer on both the Ni and the YSZ electrolyte surface, as shown in Figure 3. Even though the detailed anode reaction mechanism is not yet fully understood, optimisation of the length of the triple-phase boundary line by reducing the particle and pore size in the electrochemically-active anode layer has led to high performance SOFC cells.

While a fine-grained microstructure is necessary for the Ni-YSZ anode to achieve maximum performance, the resulting high interfacial surface area is susceptible to degradation and is therefore a serious obstacle to achieving an anode operating life of several thousands of hours under varying conditions (e.g. gas phase, electrical loading, temperature cycles). In particular the high susceptibility of Ni to coking, the re-oxidation in case of fuel loss and the sensitivity to poisoning of the electrode by sulphur are the main concerns regarding the durability and degradation of Ni-YSZ anode-supported SOFC cells.

As an alternative to Ni-YSZ cermet anodes, the focus is on electronic and mixed-ionic electronically-conducting ceramics. Developments are concentrating on mixed conducting fluorites and perovskites, and also on more complex structures such as pyrochlores, layered perovskites and tungsten bronzes [14]. The ceramics in general exhibit stability with respect to redox-cycles (fuel-air) as well as a very low, sometimes even negligible, coking activity.

Of these alternative materials, only ceria-based anodes, such as $Ce_{0.6}Gd_{0.4}O_{1.8}$ [15], and $La_{0.8}Sr_{0.2}Cr_{0.5}Mn_{0.5}O_3$ (LSCM) [14] have been developed up to the point where their performance is competitive with the Ni-YSZ cermet. By dispersing a Ni catalyst throughout the porous ceria structure, area specific resistances less than 0.06 $\ddot{\alpha}$ cm^2 at 1000 °C in hydrogen have been achieved. This is similar to the values observed in Ni-YSZ anodes. No carbon deposition has been observed at high methane content, and redox as well as long-term stability are proven. The ceria electrodes

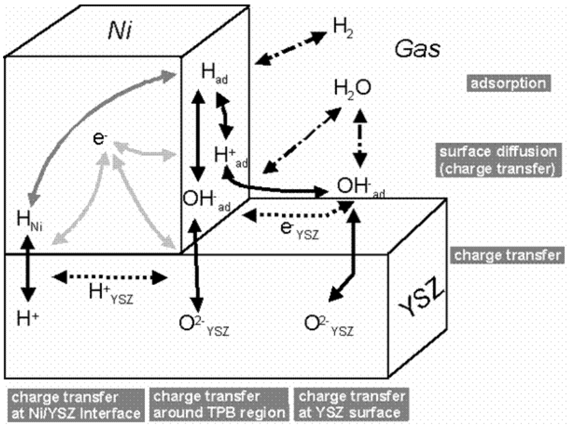

Fig. 3 Possible reaction steps in the hydrogen water reaction around the Ni/YSZ/gas exposed triple-phase boundary line.

do not fully match the CTE of the YSZ electrolyte and the electrode expands upon reduction. The problems resulting from the thermo-mechanical stresses at the ceria/YSZ interface have been overcome by introducing an anchoring construction at the interface to the YSZ electrolyte.

A disadvantage of the mixed conducting ceramics such as ceria or LSCM is the relatively low electronic conductivity which largely prevents the use of these materials at SOFC operating temperatures around 800 °C. This problem may be overcome by using cermets, in which a metallic phase acts as the current collector, instead of pure ceramic materials. Ceriabased composite anodes Cu/YSZ/ceria [16] and Ni/ceria [17] are being developed for direct application of hydrocarbon fuels. Direct feeding of methane, propane and higher hydrocarbons up to decane without carbon deposition has been reported.

With respect to compatibility with the YSZ solid electrolyte, yttrium-titania modified zirconia (YZT) is also a promising mixed-conducting fluorite, which has recently been investigated as a potential anode material. [18] The development of these advanced cermets is still at a rather fundamental stage and the materials remain to be demonstrated in cells of technologically-relevant size.

3.2
Anode Support

Due to the high electronic conductivity of Ni-YSZ cermets, relatively thick layers can easily be used as the supporting component in the SOFC cell. Besides the ability to pick up the current from the anode, the support has to be sufficiently mechanically stable and porous in order to allow the unlimited transport of the gaseous educts and products to and away from the anode. The thickness of the anode supports varies with the fabrication technique. Anode support layers of 300 ά m up to 2000 ά m thickness have been prepared by tape casting and die pressing, respectively.

The pressing technique seems to be an easy and upscalable fabrication procedure for the anode supports. Both warm and cold die pressing have been investigated. Ceramic compositions produced by the Coat Mix process have been successfully developed for warm die pressing at the Forschungszentrum Jülich and form the basis for their anode-supported SOFC development [9].

An alternative process is the cold die pressing of polymer-bonded Ni-YSZ granules. Cold die pressing has been suggested as an upscalable and cost effective technique for the fabrication of various Ni-YSZ cermet anode supports [19, 20]. The method is environmentally friendly due to the comparatively low amount of harmless organic binders used, and is upscalable for mass production. No complex debinding or drying procedure is needed prior to the firing step. The porosity of these anode supports can be tailored by controlling the particle sizes of the NiO and YSZ powders and by including additional pore-forming agents. Graphite in the form of plates and spheres with particle sizes (d_{50}) ranging from 5–50 ä m has been shown to be a suitable pore-former for water-based dispersions [20].

An important step in the fabrication of anode-supported cells and also multilayer anode supports is the cofiring of at least two layers (the electrolyte and the anode), and higher orders of multilayers. In order to avoid bending and warping of the samples, the shrinkage of the individual layers during sintering should be matched. Figure 4 shows the variation of the free shrinkage for various NiO-YSZ compositions with and without carbon as a pore former.

By controlling the shrinkage and the porosity of individual Ni-YSZ cermet compositions, multilayer structures with a gradually changing pore size have been prepared as shown in Figure 5. The concept of a gradually changing porosity in the anode support allows individual tailoring of the supporting anode layer and the electrochemically-active layer. While a coarse and open porous structure is essential for gas transport inside the anode support, much smaller pore and particle sizes leading to a greater TPB length are required towards the electrochemically-active layer. First results [20] have validated the feasibility of the concept and of the fabrication process. However, the microstructure in Figure 5 exhibits rather isolated

[20]).

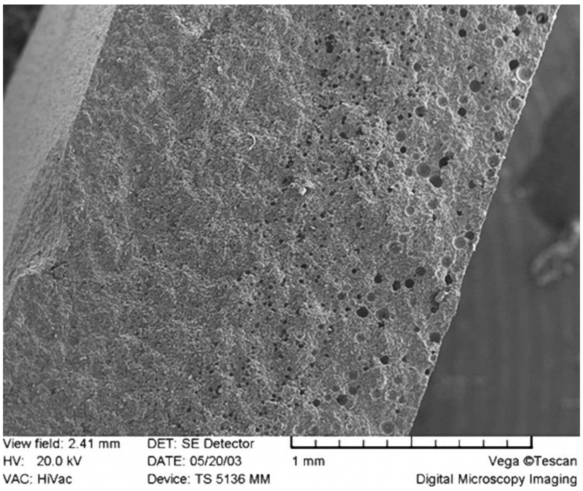

Fig. 5 Anode support consisting of four layers with graded porosity.

large pores which are not considered advantageous for gas transport through the porous anode support, thus further optimisation of the process is required.

3.3
Electrolyte

The solid oxide electrolyte must isolate the two gas atmospheres (fuel and air) from one another and transport the oxygen ions without significant losses from the cathode to the anode. The electrolyte, therefore, needs to be a sufficiently fast oxygen ion conductor and also has to be chemically stable in the large oxygen partial pressure gradient which exposes it simultaneously to highly reducing and highly oxidising conditions.

The transport of oxygen ions in the electrolyte occurs via oxygen vacancies in the oxygen sublattice. The concentration of vacancies and their mobility determines the electrolyte ion-conductivity. Among a number of oxide ion conductors, which includes ceria and La-gallate [3, 21], zirconia stabilised in the conductive cubic phase with up to 10 mol% of either yttria (YSZ) or scandia (SSZ) is the electrolyte material of choice. Fully-stabilized zirconia offers best fast oxygen ion conduction and matching secondary requirements with the other SOFC components such as chemical stability and durability. The conductivity of $Y_{0.15}Zr_{0.85}O_{1.92}$ is >0.1 S/cm at 950 °C–1000 °C and 0.03–0.003 S/cm at temperatures of 600–800 °C (temperature dependence corresponds to an activation enthalpy of 0.8 to 1 eV).

In the absence of suitable alternative materials, minimising the thickness of the YSZ layer to a few micrometers is essential to lower the SOFC operating temperature to around 800 °C. The use of nanopowders seems to be a promising approach for obtaining thin electrolyte films and also for reducing the sintering temperature. For industrial applications, organic solvents are of high interest since they are regarded as more stable and less sensitive to ambient conditions than waterbased solvent systems [22, 23, 24]. The dispersion of nanosized YSZ in organic media was recently investigated [25] in order to achieve high solids loadings in screen-printing slurries. Different long-chained organic acids and amines (dispersants) and various solvents with high boiling points were compared. The effectiveness of the dispersants was evaluated on the basis of rheological measurements, i.e. the lower the viscosity of the slurries, the better the dispersant. Organic acids show a higher dispersive efficiency compared to the amines, and the best results were obtained by using an oligomeric pentastearic acid (Solsperse 3000 (Avecia Additives)). This can be explained by considering the dispersant chain length: Pure steric stabilisation, which is needed in non-polar solvents, is achieved by adsorbed layers thicker than 10 nm, and this condition is fulfilled by the pentamer. The other dispersants, which are semi-steric dispersants, provide a layer of only about 4 nm thickness, which is not sufficient to overcome the van der Waals attraction between the particles. Regarding the solvents, slurries prepared with either kerosene or dodecane showed the lowest viscosities, but the best long-term stability was achieved by using terpineol.

Using these results, dispersions of micron- and submicronsized powders were prepared. Solids loadings as high as 57 vol% and 52 vol%, respectively, were reached (Fig. 6). With these dispersions, electrolyte layers were screen printed on anode substrates and sintered to dense layers on circular disks 12 cm in diameter. An example is shown in Figure 7. All the dispersions showed good compatibility with the substrate. The electrolyte layer could already be sintered at a temperature as low as 1300 °C (Fig. 7a). The sintered layers are between 10 and 20 α̈ m thick and contain no pinholes or cracks (Fig. 7b).

3.4
Cathodes

At the air electrode (cathode), gaseous oxygen is reduced and the resulting oxygen ions are incorporated into the electrolyte (Eq. 2).

$$O_{2,g} + 4e^- + 2V_O^{\cdot\cdot} = 2O_O^x \qquad (2)$$

The cathode environment is highly oxidising, and this fact precludes the

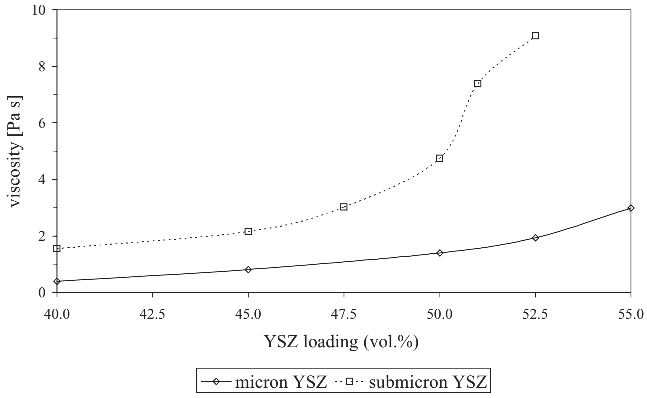

Fig. 6 Viscosity of the terpineol-Solsperse3000-zirconia dispersions as a function of powder size and solids loading.

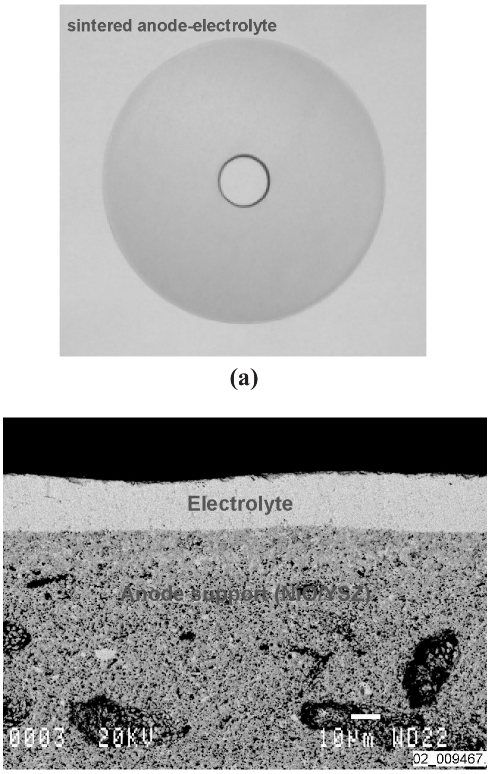

(a)

(b)

Fig. 7 Sintered electrolyte layer on the anode substrate: (a) top view, (b) cross section.

use of metals as electrode materials. The standard SOFC cathode material is an electronically-conductive oxide ceramic based on the perovskite lanthanum manganite in which La is partially replaced by Sr (i.e. $La_{1-x}Sr_xMnO_3$, or LSM). These perovskites are electronic p-type conductors for which the electrical properties are determined by the La/Sr ratio. The formation of $La_2Zr_2O_7$ and SrO is inhibited by incorporating an excess of Mn (1–10%) in the composition and keeping the sintering temperature below 1300 °C [26]. These two compounds impair cathode performance due to solid state reactions.

Significant attention has been paid to the understanding of the electrochemical process in SOFC LSM cathodes [27]. Similar to the Ni-YSZ anode, the electrochemically-active area is assumed to be around the triple-phase boundary where the electronic conducting perovskite, the YSZ electrolyte and the gas phase are in contact with each other. It is generally assumed that oxygen reduction is a multi-step reaction involving adsorption and surface diffusion in a region around the TPB (see Fig. 8).

Early attempts to optimise the LSM cathode activity were concerned with the incorporation of noble metal catalyst particles in order to facilitate −OO bond breaking [28]. A more effective development was the introduction of the composite LSM/YSZ (similar to the Ni-YSZ). Composite cathodes have been fabricated as bi-layers and functionally-graded structures using not

only conventional wet ceramics processes e.g. slurry deposition [29], but also using advanced deposition techniques such as plasma and thermal spraying [30, 31]. An electrochemical performance corresponding to 0.07–0.12 $\ddot{\alpha}\,\mathrm{cm}^2$ at 850 °C and 0.2–0.4 $\ddot{\alpha}\,\mathrm{cm}^2$ at 750 °C was achieved. Furthermore, a significant decrease in the temperature dependence of the cathodes was realised, with 140 kJ/mol being recorded for air sprayed cathodes and 70 kJ/mol for plasma sprayed cathodes (compared to 200 kJ/mol for pure LSM cathodes).

Despite these advances, there is still a need to further increase the cathodic performance for SOFC operation around 800 °C. Regarding optimisation of the cathode material, there is a fair agreement that a fast oxygen exchange reaction between the lattice oxygen and the gas phase, as well as ionic conductivity in the perovskite, would be advantageous. Thus, further mixed ionic electronic conducting perovskites have been the focus of recent R&D activities.

In the perovskite structure the chemical composition and also the oxygen stoichiometry can be varied to a large extent, and this permits tailoring of the material's electrical properties, especially the ionic conductivity and the oxygen exchange rate. Alternative perovskites based on $La_{1-x}Sr_xFeO_3$ (LSF) and $La_{1-x}Sr_xFe_{1-y}Co_yO_3$ (LSCF) have already been investigated, while the search for new or advanced materials is still going on.

Synthesis techniques that allow a variation of the chemical composition and also the powder morphology in a simple, but controlled, manner are, therefore, of high interest in the area of cathode development. Complex ternary and quaternary perovskite powders can meanwhile be produced in multiple kilogramme quantities by wet chemical processes (co-precipitation), spray processes (flame spraying, spray pyrolysis), and by solid state reaction (mixed oxides or carbonates).

A promising route suitable for such a medium size batch fabrication of complex oxides which has attracted increasing attention over the past 10 years is the spray pyrolysis method [32]. The principle is shown in Figure 9. By spraying a saturated solution of nitrate salts with the desired cation stoichiometry into a hot chamber, the desired perovskites can be prepared either directly, or by a subsequent thermal treatment of the resulting powders. As shown in Figure 10, various powder morphologies ranging from nanocrystallites to sintered microgranules can be obtained depending on the materials, the spraying conditions and the subsequent temperature treatment [33].

Tailoring the powder morphology in order to obtain a long triple-phase boundary line is an important focus for further development in the fabrication of high performance SOFC cathodes. For wet chemical processing techniques like screen printing, the use of submicron powders can serve to impart a fine, porous electrode structure. Figure 11 shows the micro-structure of a LSF-cathode prepared from spray-pyrolysed submicron powders. The performance test under technically relevant conditions indicated a significant improvement of the cell performance that was attributed to the use of nanostructured perovskite powders for the cathode [34, 35].

Although these results are encouraging, the fabrication of nanoparticles using rather simple fabrication routes carries with it the risk that the individual nano-sized grains will be of inhomogeneous chemical composition. While the average composition can be well controlled, the stoichiometry may vary on a microscopic

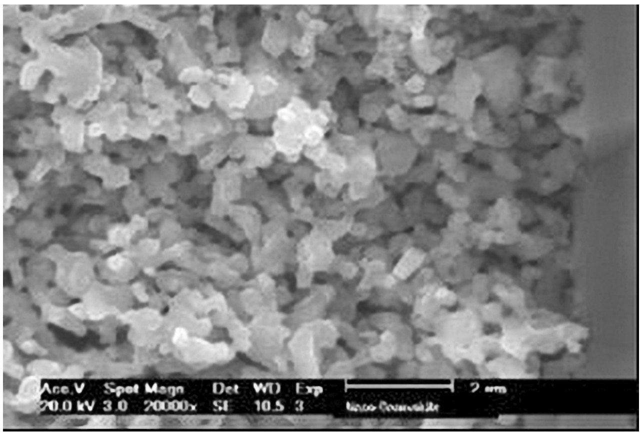

Fig. 11 SEM micrograph of an nanostructured cathode, as applied in HT ceramix SOFC cells.

level. Such inhomogeneities have indeed been observed by TEM-EDX in both spray pyrolysed and co-precipitated LSF and LSM powders [35]. It is likely that insufficient control of the seed crystal formation process is the cause. Subsequent grain growth during calcination and sintering steps are expected to homogenise the stoichiometry, however, the trend to lower heat treatment temperatures mentioned earlier means that the precise control of the nanopowder composition is becoming even more important. Possible alternative routes to produce powders with homogenous chemical compositions are the flame spray processes and combustion synthesis, where the latter is currently limited to laboratory-scale amounts of powders.

Although LSF shows promise as a SOFC cathode material, the chemical compatibility with the YSZ electrolyte has not been fully explored. Initial results have provided evidence for cation interdiffusion between YSZ and LSF, which needs to be further analysed and evaluated [36].

A well-known and highly-active cathode material is $La_{1-x}Sr_xCo_{1-y}Fe_yO_3$ (LSCF). This material is chemically incompatible with the YSZ electrolyte, with solid state reactions ocurring which can seriously deteriorate cathode performance. In order to use this material in a solid oxide fuel cell, a more complex cell arrangement and modifications to the cell fabrication process are required. An advanced cell concept for using LSCF as cathode is presented below.

4
Advanced SOFC Cell Concepts

The multilayer structure of the SOFC cell and the operating conditions impose strict requirements on the materials and the compatibility between the individual cell layers. Although there is significant research and development going on to find better and more suitable materials, not all the requirements for a given cell layer can currently be fulfilled by one single material. Engineering solutions under investigation to date include the use of composite materials such as cermets, or the use of additional layers (for instance in a bi-layer electrolyte) in order to

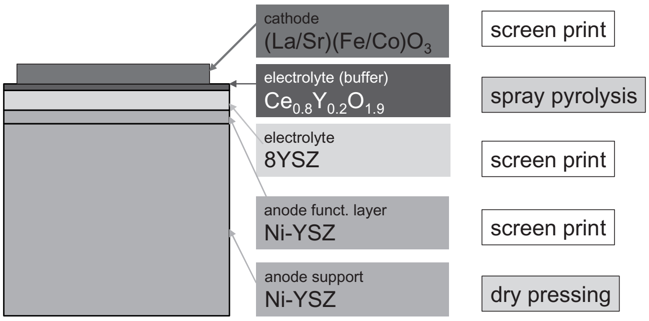

Fig. 12 Concept for advanced anode-supported cells for operation in steam-reformed natural gas at around 800 °C.

avoid direct contact between incompatible materials while maintaining the functionality of the respective layers.

An advanced concept using LSCF as a cathode material in anode supported SOFC cells by using low cost and upscalable fabrication processes has recently been presented [37]. The cell concept, presented here in Figure 12, features a Ni-YSZ anode on a anode support, and a bi-layer electrolyte layer consisting of a 20–30α̈ m thick 8-YSZ (8 mol% yttria stabilised zirconia) layer followed by a submicron yttria-modified ceria layer. The ceria acts as a so-called ‘‘barrier layer’’ to avoid contact, and thus chemical reaction, between the 8-YSZ electrolyte and the LSCF cathode.

Two alternative low-cost fabrication techniques were used to fabricate circular cells with an active cell area of 100 cm^2 of this advanced cell concept. Die pressing (see Sec. 3.2) was used to fabricate the Ni-YSZ cermet support, while ceria barrier layer was deposited using the spray pyrolysis technique (see Sec. 3.4). The technique involves spraying nitrate solutions onto a heated substrate surface where the solutions dry to salts and decompose directly to the desired ceramic phase without any subsequent firing or sintering step [38]. Dense layers with a thickness under one micron can be prepared [39]. In the advanced cell concept shown here, spray pyrolysis deposition was used to deposit thin (250 nm) barrier layers of yttria-modified ceria (CYO) on top of the screen-printed 8-YSZ electrolytes on ring-shaped cells with an inner and outer diameter of 2 and 12 cm, respectively (100 cm^2 active cell area, see also Fig. 7). The resulting microstructure of the cell is shown in Figure 13.

Such advanced cells have been assembled in a three-cell short stack in the Sulzer HEXIS design and tested in steam-reformed methane (a mixture of mainly hydrogen and carbon monoxide). The stack performance, and the performance of each individual cell, is shown in Figure 14. The open-circuit voltage is around 980 mV. Due to the absence of outer rim sealing in this stack design and the steam content in the fuel mixture, the unloaded cell voltage value confirms adequate electrolyte specifications. At 800 °C with 200 g/h cell air flow and 4 g/h cell fuel flow, a power output of 32 W/cell (320 mW/cm^2) with an electrical efficiency of 61% and a fuel utilization of 90% was achieved. The highest power output (43 W/cell, 430 mW/cm^2) resulted in an electrical efficiency of 32% and a fuel utilization of 45%. This correlates

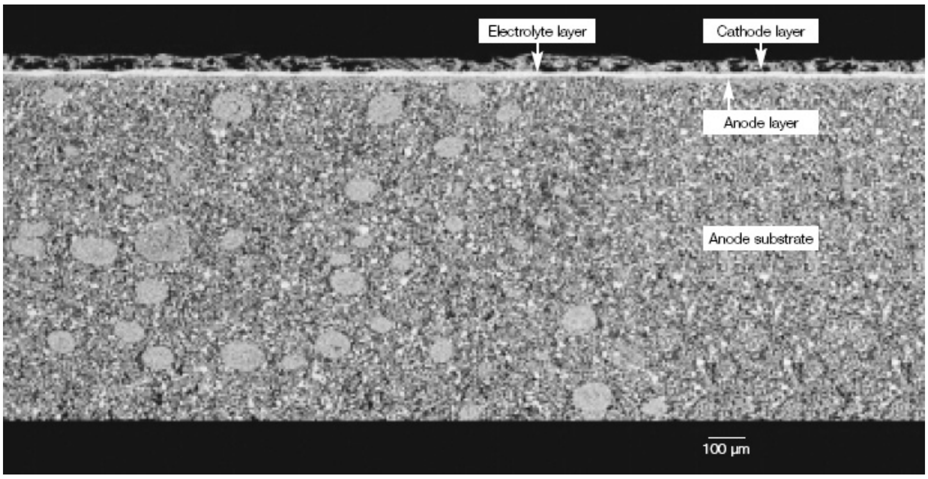

Fig. 13 Cross-section of an anode-supported cell (Ni-bidisperse YSZ)//YSZ/CYO//LSCF) after 330 h testing in steam-reformed natural gas (steam-to-carbon ratio = 2).

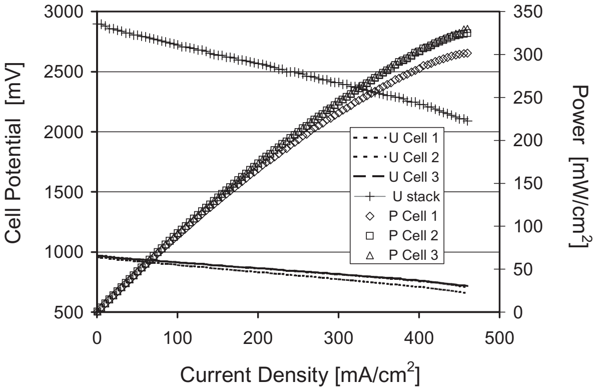

Fig. 14 Performance of a 3-cell short stack and the individual cells (Ni-bidisperse YSZ)//YSZ/CYO//LSCF) at 800 °C, natural gas flow per cell 4 g/h, air flow per cell 200 g/h.

well with the performance of the standard, electrolyte-supported Sulzer Hexis cells, which, however, are usually operated at much higher temperatures (920 °C). Therefore, a significant decrease in the operating temperature to 800 °C without losses in the electrical power output compared to the standard product has been demonstrated in these advanced anode-supported cells. A remaining challenge for this cell concept, and the techniques used for its fabrication, is the reproducibility of the cell fabrication process on a technical scale. Especially the processing of the Ni-YSZ supports needs to be further optimised.

As indicated in Section 3.1., the major functions of the anode support are current pick-up and gas transport to the active electrode layer. While the Ni-YSZ cermet was originally developed for operating temperatures between 900–1000 °C, the reduction of the operating temperature to 800 °C now allows the use of other materials such as ferritic steels, which are already used for the interconnect plate. However, conventional wet ceramic processes, especially the associated sintering steps in air at temperatures of 1300–1500 °C, still rule out the use of such steels in the cell assembly. In order to efficiently make use of metallic supports, alternative fabrication processes need to be applied.

Possible alternative cell fabrication processes for supported-solid oxide fuel cells are plasma spraying and thermal spraying [30, 31]. The plasma spray process for SOFC cells is currently being developed further by the German Aerospace Center (DLR) for both mobile (automotive) and stationary applications [40, 41]. In the plasma-spray process, the anode, cathode and electrolyte raw materials (NiO-YSZ, (La,Sr)MnO_3, and YSZ or SSZ, respectively) in the form of powders with a particle size of approximately 10–25α̈ m are injected into a high temperature plasma jet and deposited in order as the desired ceramic layers. In contrast to wet powder processing techniques, plasma spraying does not involve additional thermal treatments (e.g. a sintering step). Further advantages of the process are the high mechanical strength of the cells and the resulting thermal cycling capability, as well as the high porosity of the anode substrate, which ensures a uniform fuel supply to the electrode. For plasma sprayed cells on steel supports, power densities of 0.6 W/cm^2 in hydrogen at 900 °C have been reported [42]. At reduced temperatures of 800 °C, a maximum power of 0.23–0.35 W/cm^2 has been achieved using hydrogen as fuel [43].

5
Outlook

Even though a set of materials seems to be established for solid oxide fuel cells, the materials and processing development can by no means be considered as complete. Durability and cost reduction are major problems which still need to be solved before successful commercialisation of SOFC technology can be realised.

Presently there is a continuous trend to lower the operating temperature of the SOFC cells, and this requires that new materials and/or cell concepts need to be developed. The situation remains that no single material is known that can fulfil all requirements for a given individual cell component. Therefore, materials engineering solutions and the development of new fabrication techniques are expected to play a key role in future developments. While lower operating temperatures may allow the application of even more complex cell concepts, highly integrated processes such as the spray pyrolysis method for powder production/layer deposition, as well as thermal (plasma) spraying, also have a significant potential to further reduce fabrication costs. The various application-specific demands for small, larger-scale stationary, and especially automotive systems can be regarded as a strong and helpful "application pull" for future progress in SOFC technology.

Temperature Measurement

Joachim Fischer

1
Definition of Temperature – An Introduction

The definition of temperature was first suggested by William Thomson, later named Lord Kelvin, and it is based on the amounts of heat entering and leaving an ideal heat engine:

$$\frac{Q_h}{T_h} = \frac{Q_c}{T_c} \tag{1}$$

where Q_h is the heat flowing into the engine from a hot reservoir at a temperature T_h, and Q_c is the heat flowing out of the engine to a cold reservoir at a temperature T_c. Thomson summarized that heat provides the basis of almost all power generation, in which the efficiency increases with increase in the temperature of the hot reservoir. Clausius observed that one consequence of Thomson's temperature definition is that the sum of all of the heats flowing out of a heat engine multiplied by $1/T$ is identically zero for reversible processes and greater than zero for irreversible processes, that is,

$$\sum_i \frac{Q_i}{T_i} \geq 0 \tag{2}$$

Clausius called the new quantity, $S = Q/T$, *entropy*, being a sort of transformed energy (from the Greek word *trope*, which means transformation).

The temperature defined by Thomson was based on the conceptual device of the ideal heat engine; however, such a device is not necessary. The mathematician Carathéodory showed that in any system there exists a unique state variable that characterizes the reversibility of a process, and this variable is proportional to the integral of the heats associated with the process divided by a unique "integrating factor" (Chandrasekhar, 1967). Comparison of Carathéodory's result with Eq. (2) shows that the state variable is the entropy defined by Clausius and the integrating factor is the temperature defined by Thomson. Carathéodory's result leads to the definition of temperature:

$$\frac{1}{T} = \frac{dS}{dU} \tag{3}$$

where U is the internal energy of the system and S is the conventional entropy.

Boltzmann subsequently showed that the entropy of a system is related to the number of ways the constituent atoms and molecules can be arranged into the

digital Encyclopedia of Applied Physics.

observed macroscopic state:

$$S = k \ln P \tag{4}$$

where k is a constant and P is the probability of the system being in the observed state. In his original work, Boltzmann deduced the relation (4) without the factor k. Naturally, this leads to a temperature measured in energy units (joule); hence, in principle we do not need a separate base unit for temperature, the kelvin. However, such a temperature scale would have impracticably small ($\sim 10^{-20}$) and unfamiliar values. For this reason, Planck introduced a constant k, later named after Boltzmann, to provide the link to conventional definitions of entropy and temperature (Planck, 1921).

Equation (3) applied to various idealized systems yields thermodynamic relations that can be used to measure temperature. For example, for an ideal gas, we can derive the equation of state:

$$pV_m = N_A kT \tag{5}$$

where p is the pressure, V_m is the molar volume, and N_A is the Avogadro constant, the number of particles per mole.

The quantity kT, which occurs in the equations of state, is a characteristic energy determining the energy distribution among the particles of the system when it is in thermal equilibrium. Thus for unbound atoms, temperature is proportional to the mean translational kinetic energy. Temperature is linear and rational: equal intervals or ratios of temperature correspond to equal differences or ratios of mean kinetic energy, and a single definition is required to fix the magnitude of the temperature unit. All other temperature values must then be determined experimentlly, using a suitable thermal system and equation of state.

Today, the kelvin is defined in terms of the temperature of the triple point of water (TPW), and the Boltzmann constant k is a measured quantity. However, there is a current proposal of the Comité International des Poids et Mesures (CIPM) to define a numerical value for k, from which it follows that all temperatures, including the TPW, must be measured. Of course, the adopted value for k will be such that the temperature values will, as far as possible, remain unchanged. The determination of the Boltzmann constant applying primary thermometers is discussed in Section 13.

The ideal gas as introduced with Eq. (5) is as fictitious as the ideal heat engine. However, using a noble gas at a very low pressure, a thermometer can be constructed that really measures the so-called thermodynamic temperatures. In fact, the gas thermometer was the first thermometer to derive thermodynamic temperatures. Such kinds of thermometers, whose basic relation between the measurand and T can be written down explicitly without unknown, temperature-dependent constants being introduced, are generally called *primary thermometers* (see Sections 2–6 for further examples). Any accurate realization of the thermodynamic temperature is very time consuming and requires extreme metrological effort. A gas thermometer is appropriate only as a primary standard in fundamental laboratory measurements. On this ground and to harmonize the differing national temperature scales for the day-to-day practical use, the so-called International Temperature Scales have been developed by the

Consultative Committee of Thermometry (CCT) and adopted by the General Conference of Weights and Measures (CGPM). The International Temperature Scales reflect the most recent state of metrological accuracy and therefore they are replaced by new versions from time to time (see Sections 7 and 8). Instruments and methods to disseminate the scales to the users in science and industry are discussed in Sections 9–12.

With a few exceptions, thermodynamic temperatures are determined only to establish internationally agreed temperature scales. Only at very low temperatures, thermometers are calibrated with thermodynamic methods of measurement. The following primary thermometric methods are described in some detail: As an introduction, constant-volume gas thermometry (CVGT) is discussed in Section 2. More recent gas thermometric work is performed at Physikalisch-Technische Bundesanstalt (PTB), Germany, employing dielectric-constant gas thermometry (DCGT, Section 2.1) and at the French and Italian metrology institutes LNE-INM/CNAM, INRIM, the National Institute of Standards and Technology (NIST), USA, and the University College London (UCL), UK, using acoustic gas thermometry (AGT, Section 2.2). Noise thermometry work and Doppler-broadening techniques are discussed in Sections 3 and 4. The total and spectral radiation thermometry are described in detail in Sections 5 and 6.

2
Primary Gas Thermometry

The classical gas thermometer is based on the equation of state for an ideal gas (5) and is reviewed here to introduce the principle of a primary thermometer. Gases have been used for thermodynamic thermometry since its inception, and we shall see that they are still preeminent for much of the range, although the techniques have changed. In classical gas thermometry, the virial equation of state for a gas is used to relate pressure p and molar density $\rho (= n/V)$, of the gas to T (Figure 1).

Although many gases exhibit a nearly ideal behavior at low temperatures, in view of the desired level of accuracy the small departures from the ideal behavior must be carefully considered.

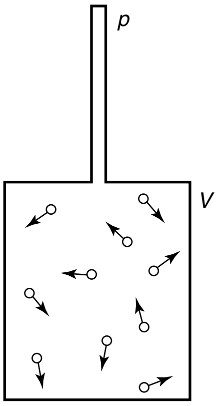

Fig. 1 Principle of constant-volume gas thermometry; pressure p and density n/V are the measurands.

This is done by measuring the relevant property that is dependent on the density. Then, the ideal behavior is deduced by an extrapolation to zero density applying an appropriate virial expansion. At sufficiently low pressures and densities, the behavior of a real gas can be described by the virial expansion, where $B(T)$ and $C(T)$ are the second and third density virial coefficients, and R is the molar gas constant:

$$pV = nRT\left(1 + \frac{B(T)}{V_m} + \frac{C(T)}{V_m^2} + \cdots\right) \tag{6}$$

For practical reasons, in primary gas thermometry, the volume is kept constant and therefore the method is called *constant volume gas thermometry* (*CVGT*). In the method of absolute pV-isotherm CVGT, the gas bulb at a constant but unknown temperature T is filled with a series of increasing amounts of gas to obtain a series of pressures p. pV/nR may be plotted as a function of $1/V_m$ according to Eq. (6). The intercept of the resulting isotherm is the temperature T. For this method, it is not necessary to know the virial coefficients because the extrapolation to zero pressure is made by fitting a virial expansion to the experimental data. There are different ways of measuring the amount of gas. One method is to weigh a bulb of known volume with and without the gas sample and deduce the amount from the weight difference. This method has not been used in recent high-precision CVGT owing to the practical difficulties inherent in the weighing of low-density gases. It was used in historical measurements at the TPW to determine the molar gas constant R. In view of the careful analysis of these measurements in Colclough (1984) and also considering systematic effects related to gas sorption, to the measurement of the gas-bulb volume, and to the pressure dilatation of the bulb, at present it does not seem possible to reach a level of relative uncertainty below about 10 parts in 10^6 (10 ppm).

Relative pV-isotherm CVGT is performed by measuring the pressures p_r and p of the same gas sample in the thermometer bulb at a known thermodynamic reference temperature T_r and the unknown temperature T. If the bulb volume V is assumed to be independent of temperature and pressure, in the case of an ideal gas, T is obtained from the following equation:

$$T = \frac{T_r p}{p_r} \tag{7}$$

However, for a real gas, the density virial coefficients have to be taken into account again. In addition, the volume of the gas bulb changes with the temperature due to the thermal expansion of the bulb material. The thermal expansion must therefore be known as accurately as possible, as it is one of the main sources of error in gas thermometry. A change in the gas pressure also causes the bulb to dilate, and this change in volume must either be calculated or the gas bulb must be surrounded by a second bulb filled with gas at the same pressure as the gas in the first bulb. In this case, the dilation of the bulb due to pressure is negligible. CVGT has been employed to establish the thermodynamic basis of the International Temperature Scale of 1990 (ITS-90) from very low temperatures up to 660 °C and is used to interpolate the scale between 3 and 25 K; for details see Fischer and Fellmuth (2005a).

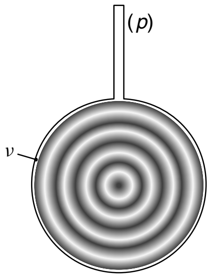

Fig. 2 Principle of acoustic gas thermometry: from the resonance frequency ν and the dimension of the resonator the speed of sound u is deduced.

2.1
Acoustic Gas Thermometers

The utility of measuring the speed of sound in gases as a primary means of measuring temperature has long been appreciated. The parameters are all intensive; hence in principle, quantities such as volumes and the amounts of gas contained in them need not be measured. Moreover, pressure need not be measured to the first order of accuracy, being only needed for evaluating the nonidealities.

For an ideal gas, the relation between the speed of sound u_0 and the thermodynamic temperature T is given by the following equation ($\gamma = C_p/C_V$ is the adiabatic exponent and M is the molar mass of the gas):

$$u_0 = \left(\gamma \frac{RT}{M}\right)^{1/2} \tag{8}$$

The pressure dependence of the speed of sound in a real gas can be expressed by a virial expansion:

$$u^2 = u_0{}^2\left(1 + \alpha p + \beta p^2 + \cdots\right) \tag{9}$$

that is, the influence of the pressure is of second order. The acoustic virial coefficients α and β can be expressed in terms of the density virial coefficients $B(T)$ and $C(T)$. As can be seen from Eq. (8), the gas constant R and the molar mass M directly influence the result. Thus, the uncertainty of T depends on their uncertainties. The influence of R and M may be eliminated if the speed of sound is determined at the temperature of the TPW with the same thermometer and the same gas, that is, if relative isotherms are measured. Applying Eq. (9), u_0 is determined by extrapolation to zero density and T is calculated using Eq. (8).

The main challenge of the method is the measurement of u with the necessary uncertainty, and in spite of significant advances this is still the limitation. In earlier works, a fixed-frequency, variable-path, cylindrical acoustic interferometer was used (Quinn, 1990; Pavese and Molinar, 1992). Such a system was used for the measurements of T in the temperature range from 4.2 to 20 K, with an uncertainty of 1–4 mK, and with a similar instrument the gas constant R was determined (Colclough, Quinn and Chandler, 1979).

Nowadays, variable-frequency, fixed-path spherical resonators are preferred (Figure 2). Their figure of merit is about an order of magnitude higher than that of cylindrical resonators. Furthermore, boundary layer effects are smaller and the problems due to the excitation of different modes are fewer. Moldover *et al.* (1988) assembled a spherical resonator and used it in 1986 to redetermine the gas constant R with an estimated relative uncertainty of 1.7 ppm, a factor of 5 smaller than the uncertainty of the best previous measurement. They measured the acoustic resonance frequencies of the argon-filled resonator and the microwave resonance frequencies of the same cavity when evacuated. The microwave data were used to deduce the thermal expansion of the cavity. More recent measurements lead to new values of $T - T_{90}$ (T_{90} temperature according to the ITS-90) between 217 and 303 K (Moldover *et al.*, 1999). Ewing and Trusler (2000) performed thermodynamic measurements in the range from 90 to 300 K. The estimated standard uncertainty ranges from 0.9 to 1.3 mK.

Later, a new spherical resonator was developed at NIST, including new acoustic transducers to cover the temperature range from 273 to 800 K. Results have been obtained for the melting point of gallium and the freezing points of indium and tin (Strouse *et al.*, 2003) and in the second experimental run between 271 and 552 K (Ripple, Strouse and Moldover, 2007). Independent acoustic measurements of the thermodynamic temperature have also been performed from 234 to 380 K by Benedetto *et al.* (2004) and from 7 to 24.5 K and from 90 to 273 K by Pitre, Moldover and Tew (2006) using spherical resonators. All results agree within the remarkably small combined uncertainty.

2.2
Dielectric-Constant Gas Thermometers

DCGT is based upon the variation with the temperature of an intensive property of the gas, the relative dielectric constant (permittivity) ε_r. The gas particles act in a capacitor as induced dipoles (Figure 3) with the static electric dipole polarizability α_0 according to the Clausius–Mosotti equation:

$$\frac{\varepsilon_r - 1}{\varepsilon_r + 2} = \frac{N}{V}\frac{\alpha_0}{3\varepsilon_0} \qquad (10)$$

where ε_0 is the exactly known electric constant and N/V is the number density. The basic idea of DCGT is to replace the density in the state equation of a gas by the dielectric constant. Thus, the state equation of an ideal gas (5) can be expressed in the following form:

$$p = \frac{kT(\varepsilon - \varepsilon_0)}{\alpha_0} \qquad (11)$$

with $\varepsilon_0\varepsilon_r = \varepsilon$ and the approximation $\varepsilon_r + 2 \approx 3$ valid for ideal gases. Therefore, DCGT avoids the density determination of the conventional gas thermometry that is complicated by the gas contained in dead spaces not at the

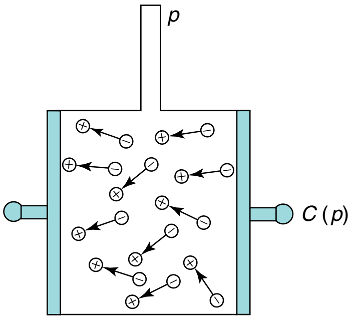

Fig. 3 Principle of dielectric-constant gas thermometry: the relative dielectric constant ε_r is determined by the change of the capacitance $C(p)$.

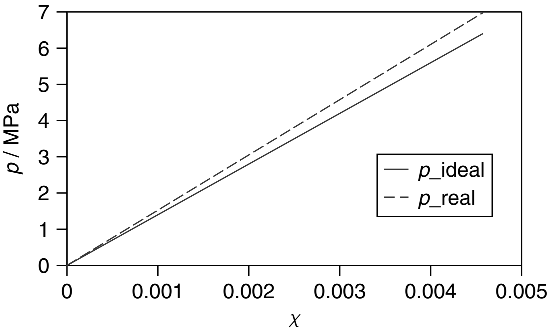

Fig. 4 Pressure versus dielectric susceptibility isotherms of helium at the TPW with (dashed curve *p*_real) and without (straight, full curve *p*_ideal) consideration of the interaction between the atoms.

measuring temperature T and by gas adsorption in the system. Other advantages are that the pressure-sensing tubes can be of any convenient size and that the thermometric gas can be moved in or out of the thermometer cell without the need to measure the amount of the gas involved.

DCGT can be used for primary thermometry in two ways. Absolute measurements require that the polarizability α_0 be known, with the required accuracy. Nowadays, this condition is fulfilled for helium, which became a model substance for evaluating the accuracy of ab initio calculations of thermophysical properties. Recent progress has decreased the uncertainty of the ab initio value of α_0 well below one part in 10^6 (Lach, Jeziorski and Szalewicz, 2004). However, one disadvantage of helium is its relatively small polarizability, which is, for instance, smaller than that of argon by a factor of 8. On the other hand, primary thermometry does not require a value of α_0 if measurements are made both at the triple point of water (T_{TPW}) and at the measuring temperature T. The ratio of the two temperatures is given by

$$\frac{T}{T_{\mathrm{TPW}}} = \left(\frac{p}{p_{\mathrm{TPW}}}\right) \frac{(\varepsilon_{\mathrm{TPW}} - \varepsilon_0)}{(\varepsilon(T) - \varepsilon_0)} \tag{12}$$

where the quantities measured at the TPW have the corresponding index.

By measuring the relative change in capacitance $(C(p) - C(0))/C(0) = \chi + (\varepsilon/\varepsilon_0)\kappa_{\mathrm{eff}}p$ of the capacitor as a function of gas pressure p, the slope $\varepsilon_0 kT/\alpha_0$ of the isotherms (11) is determined. κ_{eff} takes into account the effective compressibility of a suitable capacitor used to measure the susceptibility $\chi = \varepsilon_r - 1$. A polynomial fit to the resulting p versus χ data points (Figure 4), together with the knowledge of the dependence of the dimensions of the capacitor on $p(\kappa_{\mathrm{eff}})$, yields the temperature. Because of very small susceptibility (for instance, 0.003 at 4 K and 0.05 MPa for helium), this technique is extremely demanding for measurement of capacitance changes. For a real gas, the interaction between the particles has to be considered by combining the virial expansions of the state equation (5) and the Clausius–Mosotti equation (10) (see the dashed curve in Figure 4).

Recently, with this method, thermodynamic temperatures have been determined between 4 and 26 K (Gaiser, Fellmuth and Haft, 2007). Considering the progress in the measurement of pressure and capacitance changes, it is seen that DCGT has potential for both decreased uncertainty and increased application range. Measurements up to the TPW would be desirable because the density is measured in situ and hence the thermal expansion of the thermometer bulb does not cause problems as in CVGT. Furthermore, as an inverse application of DCGT, measurements at the TPW allow the determination of the Boltzmann constant k. The system described in Luther, Grohmann and Fellmuth (1996) would allow to achieve a standard uncertainty of k of about 15 parts in 10^6 and presently at PTB a system is under construction, which should yield an uncertainty that is an order of magnitude smaller (Gaiser, Fellmuth and Haft, 2007). Another inverse application of DCGT is the realization of a pressure standard near 1 MPa applying a toroidal cross capacitor filled with helium (Moldover, 1998). Since the interaction between the helium atoms at the realized pressure has to be considered, this project requires values calculated ab initio for both the polarizability α_0 and the second density virial coefficient.

3
Noise Thermometry

The noise thermometer is based on the temperature dependence of the mean square noise voltage, $\langle U^2 \rangle$, developed in a resistor. Nyquist derived Eq. (13) from thermodynamic calculations (Nyquist, 1928)

$$\langle U^2 \rangle = 4kTR\Delta f \tag{13}$$

valid for frequencies $f \ll kT/h$, where R is a frequency-independent resistance, Δf the bandwidth, and h Planck's constant. From the statistical nature of the measured quantity, long measuring times arise, which may be estimated from Eq. (14):

$$\frac{\Delta T}{T} \approx \frac{2.5}{\sqrt{t\Delta f}} \tag{14}$$

with t being the measuring time. One of the main problems is the accurate measurement of the very small voltages developed avoiding extraneous sources of noise and maintaining constant bandwidth and gain of the amplifiers. For details see Quinn (1990); White, Mason and Saunders (2002). In the past, in the high-temperature range, the uncertainties of noise thermometry have not been comparable to those of gas-based techniques owing to limitations from the nonideal performance of electronic detection systems. The noise generated by the wires that connect the sensor to the amplifiers has to be eliminated from the measurement. This is conveniently done by making a four-wire connection to the sensor and using two amplifier chains. The most successful technique to date is the switched-input digital correlator pioneered by Brixy *et al.* (1992) and Edler, Kühne and Tegeler (2004) (Figure 5a). The correlator is implemented by digitizing the signals from the two channels and carrying out the multiplication and averaging function by software. This eliminates the amplifier and transmission line noise superimposed on the thermal noise signal. In practial applications, the thermometer switches between a reference noise source at a reference temperature T_0 and the noise source at the unknown temperature T. The switching removes the effects of drift in the gain

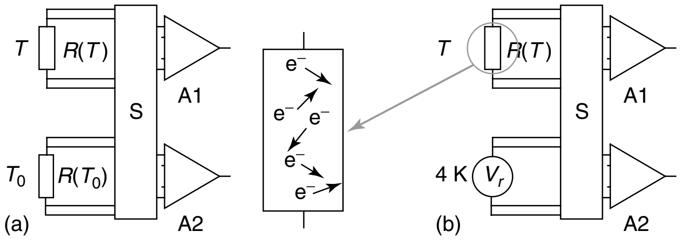

Fig. 5 (a) Block diagram for the conventional relative method with switched-input noise correlator; S, switching and A1, A2, amplification and digitization. (b) Block diagram for the new absolute method.

and bandwidth of the amplifiers and filters. A relative standard uncertainty of 2×10^{-5} at the zinc fixed point has been estimated.

The conventional switching approach does not contain sufficient free parameters to resolve the contradictory requirements for matching both the sensing resistances and the noise powers. Currently, a collaboration between NIST and MSL (Benz *et al.*, 2002) explores a new approach using the perfect quantization of voltages from the Josephson effect. This approach keeps the proven elements of the switched correlator, but separates the roles of the temperature reference and the voltage reference. The sensing resistor in the reference arm of the comparator is replaced by an AC Josephson voltage standard. A block diagram is shown in Figure 5(b). The long-term goal of the project is to build a noise thermometer with an uncertainty of 1×10^{-5} over the temperature range of 83–430 K. First steps were a proof of concept at the fixed points of gallium and water (Nam *et al.*, 2003), and a relative measurement of the zinc freezing point (Labenski *et al.*, 2007). Noise thermometry has been successfully used in the low-temperature range and the interested reader is referred to the review in Fischer and Fellmuth (2005a).

4
Doppler-Broadening Thermometry

Doppler-broadening thermometry is a standard means of diagnostics for high-temperature plasmas (Griem, 1964) and is based on the Doppler shift of the frequency of an electromagnetic wave in a moving frame of reference as compared to a frame at rest. Consider the propagation of a laser beam through an absorption cell containing an ideal gas of atoms or molecules with uniform temperature T. The Gaussian–Maxwell probability density for the velocity of the molecules v is proportional to $\exp[-(v/v_0)^2]$ with $v_0{}^2 = 2kT/m$ for atomic mass m. Around the absorption frequency ν_0, this translates into the corresponding Doppler-broadened absorption line profile with the Doppler width

$$\Delta\nu_\mathrm{D} = \left[\frac{2kT}{(mc_0{}^2)}\right]^{1/2} \nu_0 \qquad (15)$$

This relation allows the determination of the temperature by spectroscopic measurement of a Doppler-broadened absorption line profile and determination of its width. In principle, the measurement can be done using standard laser-spectroscopic techniques. As a main advantage compared to other

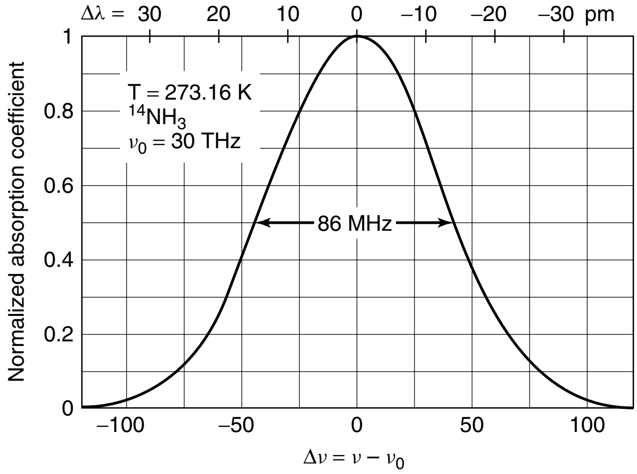

Fig. 6 Doppler-broadened absorption line profile for ammonia $^{14}NH_3$ at T_{TPW} assuming a central frequency $\nu_0 = 30$ THz.

optical methods such as absolute radiation thermometry, the Doppler profile can be determined by relative radiation measurements since it is only its width that is of interest here. Moreover, laser frequencies can be controlled with extremely small uncertainties. However, at the 10^{-6} or 10^{-7} uncertainty level, various other sources of uncertainty will have to be investigated in detail. Apart from the quadratic Doppler effect, these include, among many others, the effects brought about by interatomic interactions, notably the additional line broadening (collisional, transit time, and saturation broadening) and the reduction in Doppler broadening caused by a finite mean free path length (Dicke narrowing). Because of these, measurements may have to be performed at a series of pressure values and extrapolated to pressure zero. It should be noted that the extrapolation to zero pressure is problematic for reasons connected with the speed distribution of particles in monolayers on the cell's surface. Similarly, heating by the absorbed laser power, if it cannot be neglected at all, may require an extrapolation to vanishing laser power.

The possibility of obtaining accurate temperature values has been demonstrated (Daussy, 2007) in an experiment using an ammonia line probed by a CO_2 laser spectrometer close to 30 THz (Figure 6). The absorption signal was recorded by splitting the laser beam in two and then propagating one of the two beams through the ammonia cell for spectroscopy while the other was used as a reference beam. The two beams were amplitude-modulated by two acousto-optic modulators at two different frequencies and then recombined and focused on a single photodetector. On the basis of these preliminary results, Daussy *et al.* (2007) expect that the Doppler-broadening measurements can contribute to the determination of the Boltzmann constant with an uncertainty close to 10^{-6}.

5
Total Radiation Thermometry

It is only with the development of the cryogenic radiometer that accurate measurements of the total radiation emitted from a black body have become possible. The total radiant exitance $M(T)$ of a black body at a temperature T is given by

$$M(T) = \frac{2\pi^5 k^4}{15\, h^3 c^2} T^4 = \sigma T^4 \qquad (16)$$

where σ is the Stefan–Boltzmann constant and c the speed of light. To determine the total radiant exitance, it is necessary, for practical reasons, to make measurements over only a restricted solid angle rather than over a complete hemisphere. An aperture system must be interposed between the black body and the detector so that $M'(T) = gM(T)$, where g is the throughput of the optical system. Provided that g is independent of temperature, we may express

$$\frac{M(T)}{M(T_{\mathrm{TPW}})} = \frac{M'(T)}{M'(T_{\mathrm{TPW}})} = \left(\frac{T}{T_{\mathrm{TPW}}}\right)^4 \qquad (17)$$

where $M'(T)$ and $M'(T_{\mathrm{TPW}})$ are the quantities to be determined. Near room temperature, a measurement of the ratio $M'(T)/M'(T_{\mathrm{TPW}})$ to 1 part in 10^5 is sufficient to determine T to 1 mK or better. Quinn and Martin (1985) and Martin, Quinn and Chu (1988) have demonstrated that such measurements are possible and have obtained results between −130 and 100 °C. The principle is illustrated in Figure 7. The black body radiator at a temperature T irradiates an aperture system at liquid helium temperatures, which allows a beam of thermal radiation to enter the second black body held initially at a temperature of 2 K. The absorbing black body acts as a heat flow calorimeter or cryogenic radiometer. The radiant power absorbed in the calorimeter leads to a rise in its temperature until the radiant power absorbed is balanced to a close approximation by the heat flow along a poorly conducting heat link to a heat sink maintained at a very stable temperature near 2 K. The rise in temperature of the calorimeter is monitored. When equilibrium has been reached, a shutter at liquid helium temperature is closed, cutting off radiation from the black body radiator. At the same time, sufficient electrical power is supplied to a heater on the calorimeter to keep it at the same temperature. Provided a number of conditions are met, this easily measurable electrical power is a very precise equivalent of the thermal radiative power.

For measuring the ratio $M'(T)/M'(T_{\mathrm{TPW}})$, the following parameters of the system had to be evaluated: the emissivity of the radiator, its effective temperatures and the absorptivity of the calorimeter, the diffraction effects at the apertures, the effects of scattering of thermal radiation from surfaces between the apertures, the absorption of thermal radiation at the aperture edges, the departures from ideal geometry of the apertures, the equivalence of radiant and electrical heating of the calorimeter, the uncertainty in the measurements of the electrical power applied to the calorimeter, and the energy transfer from radiator to calorimeter by residual gas. Although some of these parameters had to be known absolutely, others needed to be known only to the extent that their dependence on the wavelength or temperature of the radiator was required. An absolute measurement of $M'(T_{\mathrm{TPW}})$ for the determination of the Stefan–Boltzmann

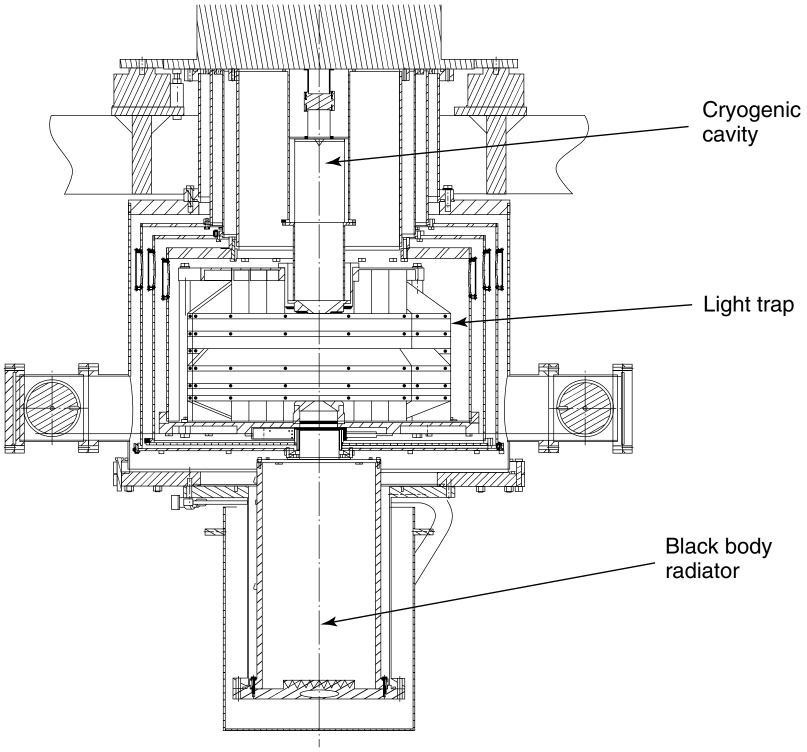

Fig. 7 Principle of cryogenic radiometer.

constant, however, would require an absolute knowledge of all of them (Quinn and Martin, 1985). The result of the determination of the Stefan–Boltzmann constant had an uncertainty of about 1.3 parts in 10^4.

Recently, NPL has built a new version of a total radiation thermometer (Figure 7), which is expected to measure σ with an uncertainty of 0.001% and thermodynamic temperatures between the Hg and Sn fixed points (Martin and Haycocks, 1998) with uncertainties of about 0.5 mK. It should be noted that the determination of σ with an uncertainty of 0.001% corresponds to the determination of the Boltzmann constant with an uncertainty of 2.5 parts in 10^6.

6
Spectral Radiation Thermometry

6.1
Relative Method Referenced to Known Temperature

As reviewed in Section 7, Eq. (18) defines the ITS-90 in the temperature range above the silver point, where $L_\lambda(\lambda, T)$ is the spectral radiance of a black body at a temperature T and wavelength λ, and c_2 is the second radiation constant. The measurement of radiance ratios can also be used to measure thermodynamic temperature if the temperature of one of the black bodies is known in terms of thermodynamic temperature as a reference. This method has been applied

to determine the temperatures of the Al, Ag, and Au fixed points of the ITS-90 and is described in the following:

$$\frac{L_\lambda(\lambda, T_{90})}{L_\lambda(\lambda, T_{90,\mathrm{ref}})} = \frac{\exp(c_2/[\lambda T_{90,\mathrm{ref}}]) - 1}{\exp(c_2/[\lambda T_{90}]) - 1} \tag{18}$$

The spectral radiation thermometer used by Jung (1984, 1986) and Fischer and Jung (1989) in the range 410–962 °C employed two simultaneously running black bodies B1 and B2. They are observed alternatively by means of a rotatable plane mirror P1 (Figure 8). One of the black bodies has the unknown temperature, and the other has the reference temperature. The radiation thermometer alternatively focused the apertures of both black bodies onto a linear detector. An interference filter defined the wavelength. The unknown temperature is calculated from the photocurrent ratio and the reference temperature using Planck's radiation law and taking into account the spectral responsivity of the radiation thermometer. During the first run of measurements, black body B1 had a reference temperature close to $T_{\mathrm{ref}} = 729$ K, a thermodynamic temperature as derived from gas thermometry (Guildner and Edsinger, 1976; Edsinger and Schooley, 1989). Black body B2, immersed in freezing aluminum, had the unknown temperature.

During the second run of measurements, black body B2, constantly running aluminum freezes, served as the reference radiator. The thermodynamic temperature T that corresponded to the temperature of black body B1 was unknown. The latter was set to values between 410 and 630 °C using standard platinum resistance thermometers (SPRTs) while the corresponding thermodynamic temperatures were obtained from the measured photocurrent ratios and the redetermined aluminum point. The results gave rise to the SPRT reference function used for the ITS-90 in the high-temperature range. Finally, during the third run, the freezing points of silver and gold have been determined (Fischer and Jung, 1989). The reference black body contained aluminum and the other one contained freezes of silver and gold, respectively.

6.2
Absolute Method

The measurement of radiance ratios does not require one to know the spectral responsivity of the radiation thermometer absolutely. However, the determination of the spectral radiance without referencing to a source of known temperature requires an instrument that has a known absolute spectral response with a well-defined geometric viewing system. This system is called, in its simplest version, a *filter radiometer* and has a set of two view-defining apertures with accurately known dimensions (Figure 9). Only recently has it become possible to measure the absolute spectral responsivity of a filter radiometer with sufficient accuracy to compete with the method used in the measurement of radiance ratios. This became possible through the use of cryogenic radiometers as primary reference standard defining a scale of spectral responsivity. The first cryogenic radiometer was constructed at NPL (Quinn and Martin, 1985) to measure the total radiation as described earlier. To establish scales of spectral responsivity, cryogenic radiometers use the spectral power of a monochromatic source, such as a laser, and subsequently calibrate the response of a transfer detector (Fox, 2002). The additional uncertainty of the calibration of the filter transmission has to be taken into account, which cannot be lower than the uncertainty of the cryogenic radiometer used for calibration. Altogether, this results in best relative uncertainties at the 10^{-4} level for this

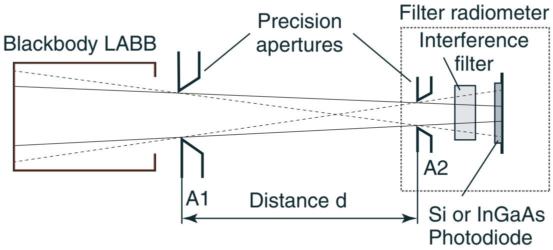

Fig. 9 Optical layout of the PTB primary radiation thermometer with the large-area black body LABB, two precision apertures A1 and A2, and the filter radiometer.

type of radiation thermometry and measurements at temperatures about 500 °C and above (Fox, 2002; Taubert *et al.*, 2003; Yoon *et al.*, 2005).

At the time of establishment of the ITS-90, there were no direct measurements of the thermodynamic temperature T above 729 K of sufficiently low uncertainty that could be used to anchor the scale. Instead, the fixed points of Al, Ag, Au, and Cu were determined through ratios of radiance using radiation thermometers as described in Section 6.1. The temperature value assigned to the reference point at 729 K (456 °C) was the mean of two separate NIST gas thermometry experiments (Rusby *et al.*, 1991). Since these two experiments differed by about 30 mK, this became the dominant uncertainty of ITS-90 realizations for all higher temperatures. This relatively large thermodynamic uncertainty of T_{90} propagates as $T^2{}_{90}$ and is thus around 50 mK at the gold point. To reduce these uncertainties, work is in progress applying acoustic thermometry (see Section 2.1) and spectral radiation thermometry.

Using absolute filter radiometry, measurements of $T - T_{90}$ in the temperature range from 660 to 962 °C (Stock *et al.*, 1996) and subsequently down to zinc-point temperatures (Hartmann, Taubert and Fischer, 2002; Taubert *et al.*, 2003; Noulkhow *et al.*, 2007) have been performed at PTB. They employed a large-area black body formed by two concentric sodium heat pipes so that the filter radiometer does not need imaging optics whose transmittance is to be calibrated (Figure 9).

A different approach is applied at NIST (Yoon *et al.*, 2005) and at NPL (Fox, 2002), where imaging filter radiometers were developed. With these systems, the thermodynamic temperatures of fixed-point black bodies with their small cavity apertures can be measured directly.

7
The International Temperature Scale of 1990

The International Temperature Scales reflect the most recent state of metrological accuracy and therefore they are replaced by new versions from time to time. The International Temperature Scale of 1927 (ITS-27) was the first to overcome the practical difficulties of the direct realization of thermodynamic temperatures by gas thermometry and the first universally acceptable replacement for the differing existing national temperature scales. Finally on 1 January 1990, the ITS-90 (Preston-Thomas, 1990a) came into force. We note that the thermodynamic temperature T (K) may also be expressed in terms of Celsius temperature t according to

$$t(^\circ\mathrm{C}) = T(\mathrm{K}) - 273.15 \qquad (19)$$

The ITS-90 accordingly defines both international Kelvin temperatures T_{90} and international Celsius temperatures t_{90} by the corresponding relation:

$$t_{90}(^\circ\mathrm{C}) = T_{90}(\mathrm{K}) - 273.15 \qquad (20)$$

Both the thermodynamic and the International Temperature Scale have the same units – the kelvin and the degree Celsius. Users sometimes prefer kelvin in the range below 273.15 K and degree Celsius above this point.

The thermodynamic basis of the ITS-90 is described in Rusby *et al.* (1991) and recommendations for its realization are given in Preston-Thomas, Bloembergen and Quinn (1990b). The ITS-90 extends upward from 0.65 K to the highest temperature practically measurable in terms of the Planck radiation law using monochromatic radiation. It is based on 17 well-reproducible thermodynamic states of equilibrium, the defining fixed points: boiling points (3–5 K with helium, 17 and 20.3 K with hydrogen), triple points (equilibrium hydrogen, neon, oxygen, argon, mercury, and water), melting point of gallium, and freezing points (indium, tin, zinc, aluminum, silver, gold, and copper). To these states, numerical values of the temperature T_{90} are assigned. These are the values that have been determined by measurements of thermodynamic temperatures T in several national metrology institutes (Rusby *et al.*, 1991). They are considered to be the best estimates at the time the scale was adopted. The defining fixed points are listed in Table 1.

Tab. 1 Defining fixed points of the ITS-90 with uncertainties $u(T_{90})$ of the best practical realization in terms of ITS-90 and uncertainties $u(T)$ of the thermodynamic temperature.

Fixed Point	T_{90} (K)	$u(T_{90})$ (mK)	$u(T)$ (mK)
Cu	1357.77	15	60
Au	1337.33	10	50
Ag	1234.93	1	40
Al	933.473	0.3	25
Zn	692.677	0.1	13
Sn	505.078	0.1	5
In	429.7485	0.1	3
Ga	302.9146	0.05	1
H_2O	273.16	0.02	0
Hg	234.3156	0.05	1.5
Ar	83.8058	0.1	1.5
O_2	54.3584	0.1	1
Ne	24.5561	0.2	0.5
e-H_2	≈20.3	0.2	0.5
e-H_2	≈17.0	0.2	0.5
e-H_2	13.8033	0.1	0.5
^{4}He	4.2221	0.1	0.3

All values are quoted as standard uncertainties. Values have been taken from Table 1.2 of the Supplementary Information for the ITS-90 (Preston-Thomas, Bloembergen and Quinn, 1990b).

7.1
Interpolating the Scale

For the first time, the ITS-90 comprises a number of ranges and subranges, throughout each of which temperatures T_{90} are defined differently. Several of these ranges or subranges overlap. In the range from 0.65 to 5 K, relations of helium vapor pressure to temperature are used to interpolate. From 3 up to 25 K, an interpolating version of the CVGT is applied to define the scale. From the triple point of equilibrium hydrogen (13.8033 K) to the freezing point of silver (1234.93 K), SPRTs are used to interpolate between the fixed points. The temperature dependence of the resistivity of high-purity platinum is too complicated for a description based only on the calibration at the available fixed points of sufficient quality (Nicholas, 1999; Quinn, 1990), but it is highly reproducible from sample to sample. Therefore, the ITS-90 prescribes two general reference functions for the ranges below and above the TPW representing a "typical" SPRT (Preston-Thomas, 1990a). Values and derivatives of the two functions are continuous at the TPW. This allows to describe the characteristic of an SPRT by the sum of a reference function and an individual deviation function. The coefficients of the deviation function are deduced from the results of the calibration at the defining fixed points of the ITS-90. The calibration can be performed for 11 subranges, which overlap more or less, using different deviation functions. To avoid the influences of the dimensions of the platinum wire, both the reference and deviation functions are specified for the resistance ratio $W(T_{90}) = R(T_{90})/R(273.16\text{ K})$, where $R(T_{90})$ is the resistance at a temperature T_{90} and $R(273.16\text{ K})$ is the resistance at the TPW. A detailed analysis of the uncertainty in the realization of the SPRT subranges of the ITS-90 is given in White *et al.* (2007).

An acceptable SPRT must be made from pure, strain-free platinum and satisfy one of the relations to be checked at the triple point of mercury ($W(-38.8344\,^\circ\text{C}) \leq 0.844235$) or the melting point of gallium ($W(29.7646\,^\circ\text{C}) \geq 1.11807$). An acceptable SPRT to be used up to the freezing point of silver (961.78 °C) must also satisfy the relation: $W(961.78\,^\circ\text{C}) \geq 4.2844$. The first two conditions guarantee a minimum purity of the platinum and the third aims at avoiding SPRTs with excessive leakage currents at high temperatures. Three types of different designs cover the SPRT range from 13.8 K to 962 °C, where the first two types have similar sensor elements:

1. The capsule-type SPRT from 13.8 to 273 K (sometimes 430 K). Characteristic data are as follows: $R(0\,^\circ\text{C}) = 25\ \Omega$, 5 mm diameter, 60 mm length, filled with 30 kPa helium at room temperature, the four platinum leads are taken out through a glass seal.
2. The conventional long-stem SPRT from −189 to 420 °C (sometimes 630 or 660 °C). Characteristic data are as follows: $R(0\,^\circ\text{C}) = 25\ \Omega$, 7 mm diameter, 600 mm length, filled with dry air. The sensors of 0.07-mm-diameter platinum wire are supported by insulators of mica, alumina, or silica.
3. The high-temperature long-stem SPRT from 0 to 962 °C (suited to −189 °C). Characteristic data are as follows: $R(0\,^\circ\text{C})$ between 0.25 and 2.5 Ω, 7 mm diameter, 600–800 mm length, filled with 90% argon + 10% oxygen at 20 kPa near room temperature. The sensors and leads are designed such as to minimize the strain on heating and cooling and the leakage through the insulation resistance. Platinum wire up to 0.4 mm diameter and insulators and sheaths of quartz are used to achieve this.

From 961.78 °C, the freezing point of silver, up to the highest practicably measurable temperatures T_{90}, is defined in terms of the ratio of the spectral radiances $L_\lambda(T_{90})$ and $L_\lambda(T_{90,\text{ref}})$ of two black bodies according to Eq. (18). One of them has the temperature T_{90} to be determined. The other has the reference temperature $T_{90,\text{ref}}$ that stands for one of the freezing points of silver, gold, or copper. The ratio is measured by means of a spectral radiation thermometer. The temperature T_{90} is calculated from the measured ratio using Planck's law for monochromatic radiation. Appropriate designs of the apparatus and good current practice of their application are extensively described in "Supplementary Information for the ITS-90" (Preston-Thomas, Bloembergen and Quinn, 1990b).

8
The Provisional Low-Temperature Scale PLTS-2000

In October 2000, the Comité International des Poids et Mesures adopted the

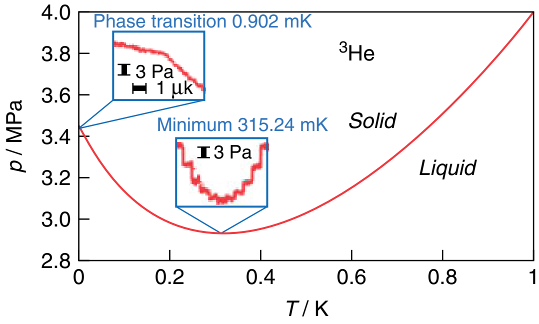

Fig. 10 Phase diagram of ^{3}He to define the Provisional Low-Temperature Scale PLTS-2000.

PLTS-2000 (CIPM, 2001). It is based on noise and magnetic thermometry performed at three institutes (Rusby *et al.*, 2002; Fellmuth, Hechtfischer and Hoffmann, 2003). Considering the uncertainty estimates for the thermometers used and the spread of the results obtained, the relative standard uncertainty of the PLTS-2000 in thermodynamic terms has been estimated to range from 2% at 1 mK to 0.05% at 1 K.

The PLTS-2000 is defined from 0.9 mK to 1 K by a polynomial with 13 terms that describes the temperature dependence of the melting pressure of ^{3}He, which is shown in Figure 10. Furthermore, four natural features on the ^{3}He melting curve can be used as intrinsic fixed points of temperature and pressure because their temperature and pressure values are also defined in the text of the PLTS-2000: the minimum pressure (315.24 mK, 2.93113 MPa), the transition to the superfluid "A" phase (2.444 mK, 3.43407 MPa), the "A-to-B" transition in the superfluid (1.896 mK, 3.43609 MPa), and the Néel transition in the solid (0.902 mK, 3.43934 MPa). The melting pressure of ^{3}He has been chosen as scale carrier for different reasons. First of all, it is a thermodynamic property of a pure substance, that is, no nonuniqueness due to a different interpolation behavior of thermometers occurs. The melting pressure can be reproduced much better than the readings of all other thermometers and a temperature range of about three decades is covered. Furthermore, apart from a narrow range near the minimum of the melting curve, a high resolution down to 0.1 µK can be achieved. The minimum is caused by the unusual fact that the entropy of the liquid phase becomes smaller than the entropy of the solid phase.

The occurrence of the intrinsic fixed points of temperature and pressure is of great importance for using the melting pressure of ^{3}He as scale carrier because melting-pressure thermometry at the highest level of accuracy requires the measurement of the pressure with an uncertainty, which is already close to that of the best national pressure standards. The use of the intrinsic fixed points decreases the uncertainty significantly since the dominating influence of the components caused by the calibration of the pressure balance applied as standard instrument of the highest quality and the hydrostatic-head correction is removed.

For the realization of the PLTS-2000, the melting pressure must be measured in situ because for temperatures below the minimum of the ^{3}He melting curve, the pressure-sensing capillary becomes blocked by solid ^{3}He. However, also above the minimum, the usual way of applying a ^{3}He melting-pressure sensor (MPS) is the "blocked capillary method," where the MPS is isolated during operation by a solid ^{3}He plug in the pressure-sensing capillary and thus the conditions are most stable. Up to now, exclusively homemade MPSs were used that are all capacitive diaphragm gauges, but differ in the detailed design (Rusby *et al.*, 2007). Recommendations concerning the facilities and procedures to be used for realizing the PLTS-2000 are given in Schuster, Hoffmann and Hechtfischer (2001). The state-of-the-art level of accuracy can be deduced from the uncertainty budgets presented in Engert, Fellmuth and Hoffmann (2004); Peruzzi and de Groot (2003).

The dissemination of the PLTS-2000 is difficult because the parameters of the available secondary thermometers cause a large uncertainty of their reading. For instance, resistance and capacitance thermometers suffer from a high instability and relatively large thermal resistances especially at temperatures below about 0.6 K. Therefore, the smallest uncertainty of the scale dissemination, being comparable with that of the scale realization, is obtained by calibrating superconductive reference samples as transfer standards for the calibration of MPSs in situ in the users' cryostats. These superconductive transfer standards can also be used for checking the parameters of other secondary thermometers together with the measuring equipment. They are of great importance for approximating the PLTS-2000 in dilution refrigerators without a demagnetization stage that do not allow to realize the three intrinsic fixed points at the lower end of the definition range (below 3 mK). The additional uncertainty component caused by the approximation may be very small if an appropriate combination of reference samples is used. For instance, it is possible to decrease this component below 20 μK in the whole range by calibrating an MPS at the minimum of the melting curve as well as at the super-to-normal-conducting transitions of tungsten (15 mK) and molybdenum (9.2 K) samples (Schuster, Hoffmann and Hechtfischer, 2001).

9
Metal-Carbon Eutectic Phase Transitions

At extremely high temperatures, most materials become so reactive that the choice of a crucible material, which does not affect the fixed-point material, becomes severely limiting. There are many types of metals with melting temperature higher than copper, the highest fixed point of the ITS-90, but none had been used successfully as practical fixed point because contamination by the graphite crucible would cause depression of the melting and freezing temperatures.

Yamada *et al.* (1999) showed that the use of metal–carbon eutectics as the fixed-point material offers a solution to the combined problem of the graphite crucible and the fixed-point materials. Graphite, the crucible material, is already a component of the fixed-point alloy and cannot cause contamination. As shown in the binary phase diagram for Ni–C in Figure 11 (Massalski, 1990), the liquid phase takes its lowest temperature at the eutectic point, and there cannot be any further depression of the freezing point by carbon contamination. The

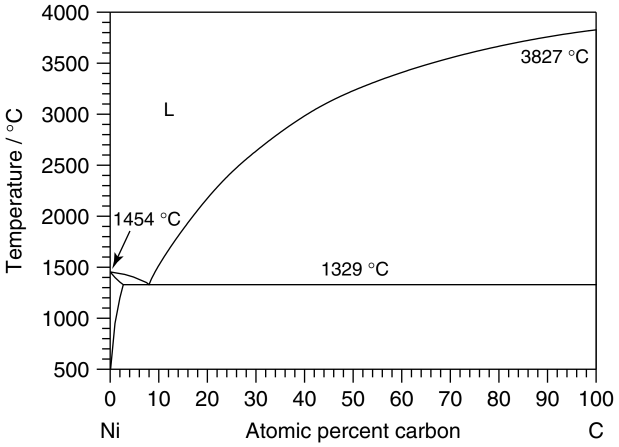

Fig. 11 Binary phase diagram of the eutectic system Ni–C, where L denotes the liquid phase.

molten metal, at slightly higher temperature than the eutectic point, would always be slightly richer in C content than the eutectic. However, solidification of graphite during the cooling would reduce the carbon content and the molten metal would reach eutectic composition when the freezing commences. Thus, reproducible plateaus are observed. There is no way to adjust the composition ratio because carbon could endlessly be supplied from the crucible. Furthermore, graphite crucibles form black bodies of high emissivity suitable for radiation thermometer calibration, and also there is no concern about reaction with the surrounding furnace material, which is also graphite.

Possible high-temperature fixed points using metal–carbon eutectics are listed in Figure 12. The melting temperatures are conveniently spaced out of the temperature range from the copper point up to 2500 °C. Metal–carbon eutectics, with no special precautions or procedures and with a wide variation in the cooling rates for the preceding freezes, have shown melting plateau repeatability of 20 mK (Woolliams *et al.*, 2006) in some cases. Evidently, material purity plays the major role as the metal–carbon eutectics appear to be more susceptible to impurities than pure-metal fixed points.

The eight metals in the box in Figure 12 are the ones that show the

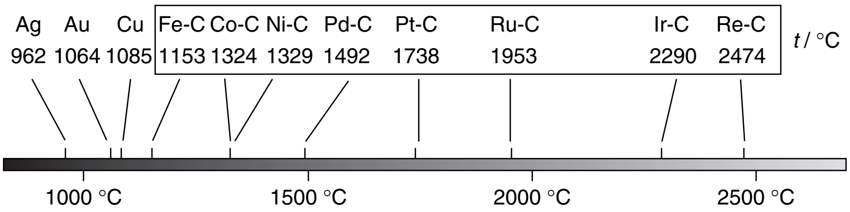

Fig. 12 Approximate melting temperatures of metal–carbon eutectic compositions. The three highest defining fixed points of the ITS-90 are shown on the left, outside the box.

simplest binary phase diagrams with carbon and are under consideration to become supplementary fixed points of the ITS-90. For most of the others, carbides are formed, which make the phase diagram complex. For instance, Ti gives TiC, with a melting temperature of 3067 °C and forms an eutectic with Ti and with graphite. The possible material combinations are Ti–TiC eutectic in a Ti (or TiC) crucible and TiC–C eutectic in a C (or TiC) crucible. The former is not easy to realize as reaction between the crucible material and the furnace material is difficult to prevent. On the other hand, TiC–C eutectic in a graphite crucible requires no additional technical improvements and is of more interest because the eutectic point has a temperature above the 3000 K mark. Other candidates are ZrC–C eutectic at 2927 °C and HfC–C eutectic at 3180 °C (Woolliams *et al.*, 2006).

In the ITS-90, the defining fixed point with the highest temperature is the copper point. Above this, no fixed point is available that can be widely used as a practical calibration device. High-temperature fixed points using metal–carbon eutectics may change this situation. The eutectics can be held in graphite crucibles, which makes the cells practical devices for use at very high temperatures. These fixed points can benefit the future high-temperature standards in various ways. They may play the role of transfer standards replacing the standard tungsten strip lamps in radiation thermometry or standard incandescent lamps in source-based radiometry. The temperature scale may be realized with much smaller uncertainty by interpolation at a selected number of these fixed points (Bloembergen *et al.*, 2003). Extension of this technique to above 3000 K is possible with metal carbide–carbon eutectics. However, the temperature values to be assigned to these new fixed points have to be determined beforehand with sufficiently low uncertainty by primary thermometry (Machin *et al.*, 2007).

10
Industrial Resistance Thermometers

Although it is not possible to develop precise formulae for the temperature dependence of the resistance of metals (Nicholas, 1999), the dependence exhibits an extremely stable and well-characterized form. Consequently, resistance thermometers are capable of quite reliable and economical industrial-quality temperature measurement. Besides nickel and copper, pure platinum proves to be the best material for most purposes; hence, the platinum resistance thermometer is the most common form of this instrument and most national standard specification codes, as well as the IEC-60751 (International Electrotechnical Commission, 1995a), are limited to platinum.

IEC-60751 defines the temperature–resistance relationship for industrial platinum resistance thermometers (IPRTs) in the temperature range of $0\,^\circ\mathrm{C} \le t \le 850\,^\circ\mathrm{C}$ by a simple quadratic equation:

$$R_t = R_0(1 + At + Bt^2) \tag{21}$$

For the range from −200 to 0 °C, an additional term is used:

$$R_t = R_0(1 + At + Bt^2 + C(t - 100)t^3) \tag{22}$$

R_0 is the resistance at the ice point, usually 100 Ω (Pt100 type). Values for the constants in these two equations are given for ITS-90, for example, in Bernhard (2004). Using these formulae, the IPRTs can be interchanged and will give temperature readings within the allowable tolerances without any calibration. For two classes of IPRTs, the temperature tolerances δt defined in IEC-60751 at a temperature t are as follows:

$$\text{class A}: \ \delta t = \pm(0.15 + 0.002|t(^\circ\mathrm{C})|)^\circ\mathrm{C} \quad (23)$$

$$\text{class B}: \ \delta t = \pm(0.30 + 0.005|t(^\circ\mathrm{C})|)^\circ\mathrm{C} \quad (24)$$

The tolerances of class A must not be exceeded in the temperature range $-200\,^\circ\mathrm{C} \leq t \leq 650\,^\circ\mathrm{C}$, and the class B values are valid in the whole usable temperature range specified by the manufacturer. In the new version of IEC-60751, which is currently in the final international adoption process, different classes with more temperature subranges, taking into account also the sensor construction, are proposed; for details see Bernhard (2004). In general, IPRTs should be considered as an alternative or replacement for liquid-in-glass thermometers when an uncertainty of better than 0.5 °C is required. It is not possible to batch IPRTs with tolerances close enough to work at a level of uncertainty of about 0.1% or better; hence, they have to be calibrated individually. Then, they may have the capability to be used as laboratory standards with uncertainties approaching 10 mK at temperatures near to room temperature.

Compared to thermocouples, IPRTs offer some advantages in sensitivity, although they are more limited in temperature range. An IPRT of the Pt100 type has an effective sensitivity of about 400 μV K^{-1} for the usually used measuring current of 1 mA. This is a factor of about 40 greater than the sensitivity of a type R or S thermocouple. The main disadvantage of an IPRT is the need of lead compensation, which usually requires three or four leads running to the sensor rather than two wires for thermocouples.

As described above, the platinum wire in the sensor of an SPRT is wound in a configuration that is as strain free as possible. This makes it rather susceptible to vibration and shock and, therefore, IPRT sensors have to be designed differently. For industrial use, in addition the sheathing must be more robust than for SPRTs. IPRT sensor constructions use often encapsulated Pt-wires wound around glass or ceramic materials whose thermal expansion coefficients match that of platinum. Cheaper sensors can be manufactured applying lithographic techniques. IPRTs of this type are available as thick-film or thin-film sensors, the latter also as an SMD. A comprehensive overview of the different constructions is given in Bernhard (2004). The direct contact between the platinum sensor element and the supporting material may cause strains or even an exceeding of the yield strength. The yield strength determines the maximum instability and corresponds to a temperature equivalent of the order of 0.5 K. Thus, the strains may cause a hysteresis of several tenths of a kelvin depending on the application range (Quinn, 1990).

So far we have described only resistance thermometers based on platinum sensor elements. For low temperatures down to about 0.5 K, that is, below the operation range of PRTs, especially rhodium–iron resistance thermometers (RIRTs) have been developed (Bedford *et al.*, 1990). Since their resistance versus temperature characteristic is complicated and nonunique, they have to be calibrated individually at 10–30 temperatures in the range from 0.5 to 30 K depending on the desired uncertainty level. RIRTs are available as precision thermometers designed similar to capsule-type SPRTs, the long-term instability of which may be of the order of only a few tenths of a millikelvin, as well as industrial thermometers with wire sensors wound on a ceramic substrate or thin-film sensors. The room-temperature resistance is between 25 and 100 Ω.

In contrast to metal-based resistance thermometers, for instance, thermistors manufactured from semiconducting metal oxides and resistance thermometers made from germanium, carbon, or some other materials show high-negative temperature coefficients of resistance. Thermistors have relative temperature coefficients of about $-0.04\,\mathrm{K}^{-1}$ near room temperature, compared with a 10-fold smaller and positive value of $+0.004\,\mathrm{K}^{-1}$ for metals. They typically can be obtained commercially with room-temperature resistances ranging from 100 Ω to 1 MΩ and can be useful for temperature measurement from −200 to 300 °C. Their high sensitivity permits use with inexpensive, direct reading instruments and, as the lead resistance is small compared to the sensor resistance, lead compensation is usually unnecessary. The characteristic of thermistors is very nonlinear and is described to a good approximation by the empirical relation based on the formula given in Steinhart and Hart (1968):

$$\frac{1}{T} = A + B\,\ln\left(\frac{R}{R_0}\right) + C\left[\ln\left(\frac{R}{R_0}\right)\right]^2 + D\left[\ln\left(\frac{R}{R_0}\right)\right]^3 \qquad (25)$$

where R_0 is a convenient reference resistance. For limited temperature ranges, measurement uncertainties below 0.1 °C can be easily obtained.

11
Thermocouples

In industry, thermocouples are the most widely used of all temperature sensors. Their basic simplicity and reliability have an obvious appeal for many applications. However, when accuracies greater than normal industrial requirements are called for, their simplicity in use is lost and their reliability cannot be assumed a priori.

The thermocouple is a device in which the difference between the electromotive forces (emfs) in its two arms gives an indication of the temperature difference between the hot and cold ends of the two wires (thermoelements). This difference is known as the *Seebeck effect*. The point of connection of the two dissimilar arms A and B, at a temperature T_1, is called the *measuring junction*, and the free ends are referred to as the *reference junction*. To permit measurements to be made of the thermoelectric potential difference between the free ends, an additional pair of identical conductors is attached, which leads to a detector. It is evident that the Seebeck effect is in no way a junction phenomenon but is, instead, a temperature-gradient phenomenon. For a proper understanding of the

Tab. 2 Thermocouple types in common use with their letter designations, typical compositions in percent weight, and temperature ranges for which tolerances apply.

Type	Thermoelements		Temperature range (°C)
	Positive	Negative	
B	Pt 30Rh	Pt 6Rh	600 to 1700
R	Pt 13Rh	Pt	0 to 1600
S	Pt 10Rh	Pt	0 to 1600
K	Chromel (Ni 9.5Cr 0.5Si)	Alumel (Ni 5(Si,Mn,Al))	−40 to 1200
N	Nicrosil (Ni 14.2Cr 1.4Si)	Nisil (Ni 4.4Si 0.1Mg)	−40 to 1200
E	Chromel (Ni 9.5Cr 0.5Si)	Constantan (Cu 44Ni)	−200 to 900
J	Fe	Constantan (Cu 44Ni)	−40 to 750
T	Cu	Constantan (Cu 44Ni)	−200 to 350

behavior of thermocouples, this cannot be overemphasized. The thermoelectric potential difference between the free ends, both at temperature T_0, is

$$E_{AB}(T_0 \to T_1) = \int_{T_0}^{T_1} [S_A(T) - S_B(T)]\,dT \qquad (26)$$

where $S_A(T)$ and $S_B(T)$ are the thermopowers of the respective conductors. $E_{AB}(T_0 \to T_1)$ is a unique function of T_0 and T_1 only if the thermoelements are homogeneous throughout the temperature gradient. The effect of the presence of an inhomogeneity is to add a small additional thermopower at the place in the thermoelement where the inhomogeneity occurs. The thermoelectric potential difference of an inhomogeneous thermocouple will be a function of its position as well as the temperature difference between the hot and cold ends. In using a thermocouple to explore the temperature gradient in a furnace, there is thus always the problem of deciding whether or not the change in potential difference, as the thermocouple is moved, indicates the presence of a temperature gradient in the furnace or an inhomogeneity in the thermocouple. Fortunately, it is usually possible to place an upper limit on the size of the effects of inhomogeneities.

Over 20 different types of thermocouples are extensively used and, of these, 8 have been standardized, with their emf–temperature relationships represented by internationally recognized standard reference functions (International Electrotechnical Commission, 1995b). The metals used in the standardized thermocouple types are given in Table 2, with the letters that identify them and the temperature ranges for which tolerances apply (International Electrotechnical Commission, 1989). In general, the tolerances are higher than those for IPRTs and are in the order of 1 K.

The thermocouples mentioned in Table 2 fall into three groups. The first is the rare-metal group, comprising types B, R, and S, based on platinum and its alloys with rhodium. They are the most accurate of the tabulated thermocouples and may be used at higher temperatures, but they are more expensive and are particularly sensitive to contamination.

The second group consists of the two nickel-based thermocouples, types

N and K. They are preferred for most applications not requiring the higher temperature limit or accuracy of the rare-metal thermocouples. The choice between types N and K depends especially on whether they are in the bare-wire or the mineral-insulated, metal-sheathed (MIMS) form. In the MIMS configuration, the thermoelements, their insulation, and a sealed sheath are integrated into a flexible cable. In contrast, bare-wire thermocouples, insulated in loose-fitting beads, are exposed to the local atmosphere and are vulnerable to the effects of oxygen, carbon, sulphur, and so on.

The third group, comprising the types E, J, and T, is based on the use of constantan as the negative arm. Constantan has the most negative value of thermopower; hence, the net thermopowers for these thermocouples are high.

Besides the standardized thermocouples, the elemental thermocouples – those whose thermoelements are pure elements – need to be mentioned. A detailed review of the recent developments of elemental thermocouples is given in Bentley (1998). A pure element is more homogeneous and thermoelectrically more stable than an alloy, because it is free of effects that arise from lattice ordering, selective volatilization, and oxidation. The most stable thermocouple is Au/Pt, although its use is limited to temperatures below about 1000 °C. The instabilities in Pt/Pd are greater, mainly due to inhomogeneity effects in the Pd wire. For example, the drift of a Pt/Pd thermocouple may be as low as 0.02 °C for 200 h at 963 °C (Burns and Ripple, 1996). Even so, these changes are about 10 times smaller than that would occur in a type R or S thermocouple under the same conditions.

Above 1750 °C, the most useful thermocouples are those based on W and Re. There are several thermocouple combinations in this category, such as W and various alloys from W 3Re to W 26Re. Their main difficulty is that on heating above recrystallization temperatures, they become brittle. The recrystallization temperature of W is 1200 °C and it has the greatest embrittlement problem, whereas W 26Re contains enough Re so that there is no problem of this kind. The thermocouple combination W 5Re versus W 26Re is possibly the best choice. It should not be used in air, but in a vacuum, in an inert atmosphere, or in dry hydrogen. Its upper limit for reliable operation is considered to be 2760 °C.

12
Radiation Thermometers

The use of noncontact temperature measurement by radiation thermometers has increased considerably in the last few years. Accordingly, a wide variety of different designs of radiation thermometers for laboratory and industrial use is available. In contrast to the procedure prescribed in ITS-90, for most practical radiation thermometers, there is no direct comparison against a reference black body of known temperature. Rather, the thermometers make use of the stability of their built-in detectors and after a calibration of their sensitivity against a temperature standard of the ITS-90 they read directly in temperature.

Practical total radiation thermometers, operating at room temperature, are the simplest radiation thermometers consisting generally of a very basic imaging system restricting the field of view with an aperture. The detector is usually a

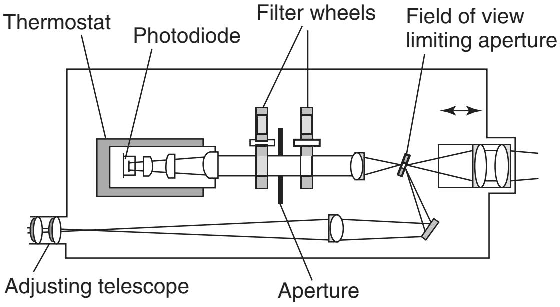

Fig. 13 Optical layout of the high-precision radiation thermometer LP3.

thermopile bolometer, which measures the rise in temperature of a blackened disk and allows the detection of the whole radiated spectrum. Because of their comparatively low sensitivity, they are, on the other hand, the most sensitive of the radiation thermometers to emissivity variations of the target. For example, a 10% overestimation of the emissivity will result in a 2.5% underestimation of the absolute temperature.

Spectral-band radiation thermometers use a filter to selectively measure only thermal radiation in a narrow band as described in Section 6. A relative bandwidth ($\Delta\lambda/\lambda$) less than a few percent is typical. Usually a silicon-semiconductor detector is used. Spectral-band radiation thermometers are used to overcome surface emissivity problems. In this case, the center wavelength λ is chosen to be as short as possible while still giving enough signal. From Eq. (18) it is derived that typically for this kind of radiation thermometers $c_2/\lambda T \cong (10-20)$, so that a 10% overestimation of the emissivity will lead to only a (0.5–1)% underestimation of the temperature.

The most common bands are around 0.65 μm for temperatures above 700 °C and 0.85–0.9 μm for temperatures above 500 °C. The design of the high-precision radiation thermometer LP3, widely used in national metrology institutes, is shown in Figure 13 (Fischer *et al.*, 2002). For lower temperatures, longer wavelengths and different detectors are applied. For example, at 3.43 μm many plastics have high absorptance. A radiation thermometer operating at this wavelength will thus see even a very thin plastic film as opaque and having high emissivity, allowing accurate temperature measurements during the manufacturing process at 200–300 °C.

The thermal radiation emitted by objects around room temperature is comparatively low and exclusively in the infrared (IR). To obtain sufficient signal, most radiation thermometers will use a wider band of wavelengths. Atmospheric absorption of IR radiation limits the choice of bands to mainly two windows, the (3–5) μm band and the (8–14) μm band. Pyroelectric or thermoelectric detectors are used to detect the radiation, and the wavelength range is often set by the transmission of the optics materials. Since the filter defining the spectral sensitivity, the optics, and the apertures will also radiate energy in this wavelength region, there must be some form of background temperature compensation within the instrument. Some instruments solve this problem by using a rotating sector disk providing a reference signal of known temperature. Recently, there has been considerable progress in the instrumentation for the calibration of low-temperature radiation thermometers (Hollandt *et al.*, 2003/4).

13
New Definition of the Kelvin

Experimentally testing of the fundamental laws of physics involves, in practice, the precise determination of the fundamental constants appearing in the laws. Since they are ultimately related to the physical units, the precise experimental realization of the latter is an unavoidable prerequisite for the progress in the development of our physical understanding of nature. Precision experiments relating the (space- and time-independent) fundamental constants to the system of units guarantee stability and reproducibility. The essence of current activities is that prototypes, which may vary uncontrollably with time and location, are replaced by abstract experimental prescriptions that relate the units to the constants. This ensures that the requirement of invariance with space and time is fulfilled. This approach is shown here for the definition of the kelvin and the Boltzmann constant. The unit of temperature T – the kelvin – is presently defined by the temperature of the TPW. Thus, the kelvin is linked to a material property. Instead, it would be advantageous to proceed in the same way as with other units: to relate the unit to a fundamental constant and fix its value. By this no temperature value and no measurement method would be favored. For the kelvin, the corresponding constant is the Boltzmann constant k, because temperature always appears as thermal energy kT in fundamental laws of physics.

As shown by the recently published CODATA values for fundamental physical constants (Mohr, Taylor and Newell, 2008), the 2006 recommended value of the Boltzmann constant k with $u_r(k) = 1.7 \times 10^{-6}$ is to a very large extent determined by the NIST result (Moldover *et al.*, 1988) and, therefore, is not yet regarded as sufficiently corroborated to replace the present definition of the kelvin. The important point to note here is that the measurement uncertainty of any value of k would be transferred to the value of T_{TPW} if that k value were taken to be the exact value of the Boltzmann constant and used to define the kelvin. Hence, if the 2006 CODATA recommended value is be fixed as the exact value of k in future, the best estimate of T_{TPW} would still be 273.16 K. However, this value would no longer be exact (as it is now as a result of the current definition of the kelvin) but would become uncertain by $u_r(T_{\mathrm{TPW}}) = 1.7 \times 10^{-6}$, which corresponds to 0.46 mK.

Considering the uncertainty estimates in the sections mentioned earlier, the two most promising methods for the reduction in the uncertainty of k currently are DCGT (Section 2.2) and AGT (Section 2.1). Doppler-broadening thermometry (Section 4) utilizing radiation measurements has only recently been proposed for the purpose of determining the Boltzmann constant (Daussy *et al.*, 2007) and is presently under investigation at the University Paris North, France, with respect to the uncertainty that can possibly be achieved. In a joint project of the universities of Milan and Naples (Fellmuth and Fischer, 2007), Italy, a similar experiment is under development. They will determine the Doppler broadening of an absorption line of water vapor probed by a diode-laser-based spectrometer system in the near IR. It seems to be possible that the DCGT method at PTB or the AGT work of different groups will have been advanced so far by the end of 2010 that they can contribute to an improved value of k or R with similar relative uncertainty as that obtained by Moldover *et al.* (1988) with the AGT in 1988. Thus, an improved value of the Boltzmann constant proposed for the definition of the kelvin would ideally have been determined by at least these two fundamentally different methods and be corroborated by other – preferably optical – measurements with larger uncertainty. We shall assume here that the experiments currently underway to measure R or k (Fellmuth, Gaiser and Fischer, 2006) will achieve a relative standard uncertainty by the end of 2010, which is a factor of about two smaller than the current u_r of approximately 2×10^{-6}, so that $u_r(T_{\mathrm{TPW}})$ will be reduced to about 1×10^{-6}, corresponding to about 0.25 mK, and that this will be small enough for the redefinition of the kelvin to be adopted by the 24th CGPM in 2011.

In the discussion about the new definition of the kelvin, it should also be recognized that the "practical" ITS-90 is a defined temperature scale that assigns an exact temperature value T_{90} to each defining fixed point. Hence, the ITS-90 value of the TPW temperature will remain 273.16 K, that is, $T_{\mathrm{TPW-90}} = 273.16$ K exactly. The value and uncertainty of T_{TPW} would only need to be taken into account if for some critical reason one has to know how well the thermodynamic temperature scale is represented by the ITS-90 at a particular temperature or in a particular temperature range. In fact, although the consistency of T_{TPW} as realized by different TPW reference cells can be as low as 50 μK and even less if the isotopic composition of the water used is taken into account (Strouse and Zhao, 2007), the uncertainties of the thermodynamic temperatures of all other defining fixed points, which are the basis for all practical thermometry, are significantly larger. In contrast to other units, the uncertainty of the realization of the kelvin varies greatly with temperature: at 1300 K, for instance, the uncertainty is roughly 100 times greater than at T_{TPW}. Hence, the fact that T_{TPW} will not be exactly known but have a standard uncertainty of 0.25 mK will have negligible practical consequences (Fischer *et al.*, 2007).

To put the new definition of the kelvin into practice, a *mise-en-pratique* has already been recommended to the CIPM by the CCT Recomm T3. The *mise-en-pratique* will allow direct determination of thermodynamic temperatures particularly at temperatures far away from the TPW in parallel to the realization described in the International Temperature Scale. In the high-temperature range, this will considerably reduce the uncertainty of the realization of the kelvin for many purposes for which the need to refer back to the TPW is anomalous, such as radiation thermometry.

In Mills *et al.* (2006), new definitions are suggested for each of the units kilogram, ampere, kelvin, and mole to be chosen by the CGPM in 2011. The following definition for the kelvin was proposed for the first time in Fischer *et al.* (2005b) and could be as simple as "The kelvin is the change of thermodynamic temperature that results in a change of the thermal energy kT by exactly $1.3806504 \cdot 10^{-23}$ joule."

Glossary

Black Body: Radiation source whose emission spectrum depends besides wavelength only on temperature and not on material properties.

Boltzmann Constant: Conversion factor between thermal and mechanical energy.

Calibration: Comparing the reading of an instrument with a standard.

Cryogenic Radiometer: Electrical substitution radiometer operated at cryogenic temperatures.

Emissivity: Ratio of radiance emitted by an object to the radiance emitted by a black body of the same temperature.

Gas Thermometer: Measures temperature by the variation in volume or pressure of a gas. The common apparatus is a constant-volume thermometer CVGT. Consists of a bulb connected by a capillary tube to a manometer.

Noise Thermometer: Measures temperature by the electronic noise generated by the thermal agitation of electrons inside an electrical conductor.

Primary Thermometer: Thermometer whose basic relation between the measurand and temperature can be written down explicitly without having to introduce unknown, temperature-dependent constants.

Radiation Thermometer: Measures temperature by detecting heat radiation.

Resistance Thermometer: Measures temperature by using the dependency of its own resistance on temperature developed across the metal.

Secondary Thermometer: Thermometer that needs calibration against a primary thermometer.

Thermocouple: A device for measuring temperature based on the junction of two dissimilar metals that have a voltage output proportional to the difference between the hot junction and the cold junction (lead wires).

Thermodynamic Temperature: Temperature of a state of equilibrium measured by a primary thermometer.

Introduction to Radiation Detectors

Claus Grupen

1
Introduction

The development of particle detectors practically starts with the discovery of radioactivity by Henri Becquerel in the year 1896. He noticed that the radiation emanating from uranium salts could blacken photosensitive paper. Almost at the same time (1895), X rays, which originated from materials after the bombardment by energetic electrons, were discovered by Wilhelm Conrad Röntgen.

The first nuclear-particle detectors were thus extremely simple. Also, the zinc-sulfide scintillators in use at the beginning of the twentieth century were very primitive. They were used, for example, for the study of scattering of α particles from nuclei. This technique required tedious and tiresome optical registration of scintillation light with the human eye.

Scintillations in the form of ‘‘northern lights’’ (aurora borealis) had already been observed since long. This fluorescence is due to charged solar particles entering the Earth’s atmosphere along the magnetic field lines at the geomagnetic poles causing excitations of nitrogen and oxygen atoms. Also, already about 50 years before the discovery of Cherenkov radiation, Heaviside (1892) showed that charged particles, moving faster than light in a transparent medium with refractive index n, emit an electromagnetic radiation at a certain angle with respect to the particle direction. Madame Curie, too, noticed a faint light emitted from concentrated solutions of radium in water, thereby unknowingly operating the first Cherenkov detector. The human eye can also act as Cherenkov detector. This has been shown by light flashes experienced by astronauts with eyes closed during their space missions. These light emissions are caused by energetic primary cosmic rays passing through the vitreous body of the eye.

In the course of time, the measurement methods have been greatly refined. Nowadays, it is generally insufficient to only detect particles and radiation. One wants to identify their nature, that is, one would like to know whether one is dealing, for example, with electrons, muons, pions, or energetic γ rays. In addition, accurate energy and momentum measurements are often required. For the majority of applications, an exact knowledge of the spatial coordinates of particle trajectories is of interest.

The trend of particle detection has shifted in the course of time from optical measurement to purely electronic means. In this development ever higher resolutions, for example, of time, spatial reconstruction, and energy resolutions, have been achieved. Early optical detectors, like cloud chambers, only allowed rates of one event per minute, while modern devices, like fast organic scintillators, can process data rates in the gigahertz regime. With gigahertz rates, new problems arise and questions of radiation hardness and aging of detectors become an issue.

Originally, particle detectors were used in cosmic rays and nuclear and particle physics. Meanwhile, these devices have found applications in medicine, biology, environmental science, metrology, radiation protection, oil exploration, civil engineering, archaeology, and arts, to name a few. While the most sophisticated detectors are still developed for particle physics and astroparticles, practical applications often require robust devices, which also function in harsh environments.

Radiation detectors have contributed significantly to the advancement of science. New detection techniques, like, for example, cloud chambers, bubble chambers, multiwire proportional and drift chambers, and micropattern detectors allowed essential discoveries. The development of new techniques in this field was also recognized by the award of a number of Nobel prizes (Charles T.R. Wilson, cloud chamber, 1927; Pavel A. Cherenkov, Ilja M. Frank, Igor J. Tamm, Cherenkov effect, 1958; Donald A. Glaser, bubble chamber, 1960; Luis W. Alvarez, bubble-chamber analysis, 1968; Georges Charpak, multiwire proportional chamber, 1992; Raymond Davis Jr., Masatoshi Koshiba, Riccardo Giacconi, novel detection techniques for neutrinos and X rays, 2002).

In this chapter, only a brief overview over the main radiation detectors is given. Within the scope of this chapter, the basic interaction mechanisms, which form the basis of radiation detectors, are only sketched.

2
Historical Detectors

Historical radiation detectors are mainly optical devices that have been used in the early days of cosmic rays and particle physics (Galison, 1997). Even though some of these detectors have been "recycled" for recent elementary particle physics experiments, like nuclear emulsions for the discovery of the τ neutrino (2000) or bubble chambers with holographic readout for the measurement of short-lived hadrons, these optical devices are nowadays mainly integrated into demonstration experiments in exhibitions or employed as eye-catchers in lobbies of physics institutes.

2.1
Cloud Chambers

The expansion cloud chamber ("Wilson chamber") is one of the oldest detectors for track and ionization measurement. The positron (1932) and the muon (1937) have been discovered in a cloud-chamber experiment. A cloud chamber is a container filled with a gas–vapor mixture (e.g., air–water vapor or argon–alcohol) at the vapor saturation pressure. If a charged particle traverses the cloud chamber, it produces

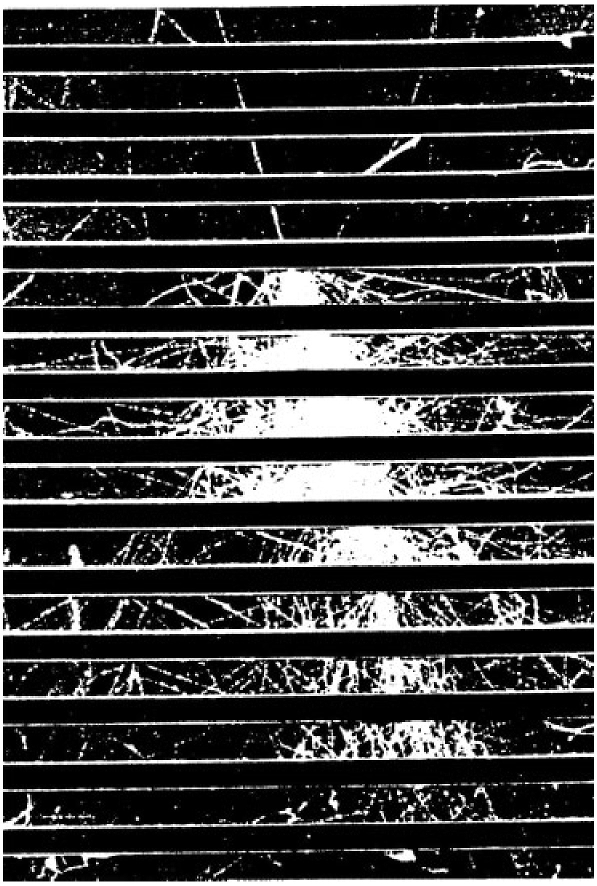

Fig. 1 Example of an electromagnetic cascade in a multiplate cloud chamber; Rochester and Turver, 1981. Private communication by G.D. Rochester; photo credit George D. Rochester.

an ionization trail. The lifetime of positive ions produced in the ionization process in the chamber gas is relatively long (approximately a few milliseconds). Therefore, after the passage of the particle a trigger signal, for example, can be derived from a coincidence of scintillation counters, which initiates a fast expansion of the chamber. By means of adiabatic expansion, the temperature of the gas mixture is lowered and the vapor gets supersaturated. It condenses on nuclei, which are represented by the positive ions yielding droplets marking the particle trajectory. The track consisting of droplets is illuminated and photographed (Figure 1).

In contrast to the expansion cloud chamber, a diffusion cloud chamber is permanently sensitive. The chamber is, like the expansion cloud chamber, filled with a gas–vapor mixture. A constant temperature gradient provides a region where the vapor is in a permanently supersaturated state. Charged particles entering this region produce a trail automatically without any additional trigger requirement. Zone widths (i.e., regions in which trails can form) with supersaturated vapor of 5–10 cm can be obtained. A clearing field removes the positive ions from the chamber.

2.2
Bubble Chambers

The bubble chamber allows the recording and reconstruction of events of high complexity with high spatial resolution. Therefore, it is perfectly suited to study rare events (e.g., neutrino interactions). In a bubble chamber, the liquid gas (hydrogen, deuterium, neon, or Freon, etc.) is held in a pressure container close to the boiling point. Before the expected event, the chamber volume is expanded by retracting a piston. The expansion of the chamber leads to a reduction in pressure, thereby exceeding the boiling temperature of the bubble-chamber liquid. If in this superheated liquid state a charged particle enters the chamber, bubble formation sets in along the particle track. The positive ions produced by the incident particles act as nuclei for bubble formation. The lifetime of these nuclei is too short to trigger the expansion of the chamber by the incoming particles. For this reason, the superheated state has to be reached before the arrival time of the particles. Therefore bubble chambers can only be used at accelerators, where the arrival time of particles in the detector is known and, therefore, the chamber can be expanded in time.

In the superheated state, the bubbles grow until the growth is stopped by a termination of the expansion. At this moment, the bubbles are illuminated by light flashes and photographed (Figure 2). The inner walls of the container have to be extremely smooth so that the liquid ''boils'' only in those places where bubble formation should occur, namely, along the particle trajectory, and not on the chamber walls. In order to measure short lifetimes in bubble chambers, the size of the bubbles must be limited. This means that

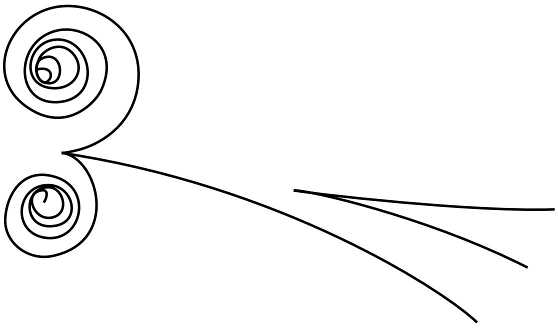

Fig. 2 This event shows the creation of an e^+e^- pair by a photon in the Coulomb field of an electron and an e^+e^- pair created in the field of a nucleus. In the first case, the target electron gets a substantial recoil and leaves a high-momentum track; Close and Marten, 1987. Photo credit Frank Close 2007.

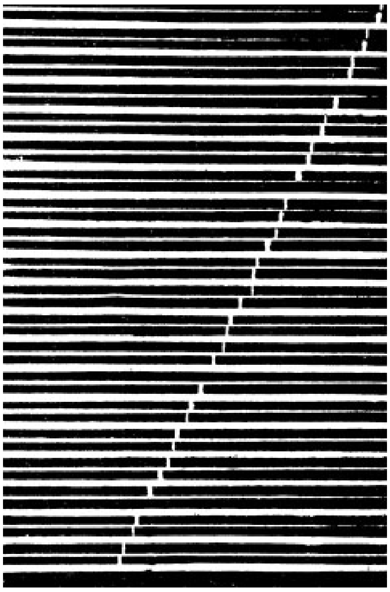

Fig. 3 Track of a cosmic-ray muon in a multiplate spark chamber; Kaftanov and Liubimov, 1963. Private communication by V.S. Kaftanov; photo credit Vitali S. Kaftanov.

the event under investigation must be photographed relatively soon after the onset of bubble formation when the bubble size is relatively small, thereby guaranteeing a good spatial resolution and, as a consequence, also good lifetime resolution for unstable particles. In any case, the bubble size must be small compared to the decay length of the particle.

2.3
Spark Chambers

In a spark chamber, a number of parallel plates are mounted in a gas-filled volume. Typically, a mixture of helium and neon is used as counting gas. Alternately, the plates are either grounded or connected to a high-voltage supply. The high-voltage pulse is normally triggered to every second electrode by a coincidence between two scintillation counters placed above and below the spark chamber. The gas amplification is chosen in such a way that a spark discharge occurs at the point of the passage of the particle (Figure 3). This is obtained for gas amplifications between 10^8 and 10^9. For lower gas amplifications sparks will not develop, while for larger gas amplifications sparking at unwanted positions (e.g., at spacers that separate the plates) can occur. The discharge channel essentially follows the electric field. Up to an angle of 30°, the conducting plasma channel can, however, follow the particle trajectory (track spark chamber). Between two discharges, the ions produced are removed from the detector volume by means of a clearing field. If the time delay between the passage of the particle and the high-voltage signal is less than the memory time of about 10 microseconds, the efficiency of the spark chamber is close to 100%. A clearing field, of course, removes also the primary ionization from the detector volume. For this reason, the time delay between the passage of the particle and the application of the high-voltage signal has to be chosen as short as possible to reach full efficiency. Also, the rise time of the high-voltage pulse must be short because otherwise the leading edge acts as a clearing field before the critical field strength for spark formation is reached.

2.4
Nuclear Emulsions

Tracks of charged particles in nuclear emulsions can be recorded by the photographic method. Nuclear emulsions consist of fine-grained silver-halide crystals (AgBr and AgCl), which are embedded in a gelatin substrate. A charged particle produces a latent image in the emulsion. Owing to the free charge carriers liberated in the ionization process, some halide molecules are reduced to metallic silver in the emulsion. In the subsequent development process, the silver-halide crystals are chemically reduced. This preferentially affects those microcrystals (nuclei) that are already disturbed and partly reduced. These are transformed into elemental silver. The process of fixation dissolves the remaining silver halide and removes it. Therefore the charge image, which has been transformed into elemental silver particles, remains stable.

The evaluation of the emulsion is usually done under a microscope, but it can also be performed by using a charge-coupled-device (CCD) camera and a semiautomatic pattern-recognition device. Fully automated emulsion-analysis systems have also been developed. The sensitivity of the nuclear emulsion must be high enough so that the energy loss of minimum-ionizing particles is sufficient to produce individual silver-halide microcrystals along the track of a particle. Commercially available photoemulsions do not have this property. Furthermore, the silver grains that form the track and also the silver-halide microcrystals must be sufficiently small to enable a high spatial resolution. The requirements of high sensitivity and low grain size are in conflict and, therefore, demand a compromise. In most nuclear emulsions, the silver grains have a size of 0.1–0.2 μm and so are much smaller than in commercial films (1–10 μm). The mass fraction of the silver halide (mostly AgBr) in the emulsion amounts to approximately 80%. Nuclear emulsions allow high spatial resolution of complex events with large multiplicities. They are permanently sensitive and cannot be triggered.

2.5
Track-Etch Detectors

Particles of high electric charge destroy the local structure in a solid along their tracks. This local destruction can be intensified by etching and thereby made visible. Solids such as inorganic crystals, glasses, plastics, minerals, or even metals can be used for this purpose. The damaged parts of the material react with the etching agent more intensively than the undamaged material and characteristic etch cones will be formed. If the etching process is not interrupted, the etch cones starting from the surface will merge and form a hole at the point of the particle track. The etching procedure will also remove some part of the surface material.

Track-etch detectors show a threshold effect: the minimum radiation damage caused by protons and α particles is frequently insufficient to produce etchable tracks. The detection and measurement of heavy ions, for example, in primary cosmic rays ($Z \geq 3$), will consequently not be disturbed by a high background of protons and α particles. The size of the etch cones (for a fixed etching time) is a measure of the energy loss of the particles. Therefore, if the velocity of the particles is known, it allows a determination of the charge of the nuclei. A stack of track-etch detectors, flown in a balloon at a residual atmosphere of several grams per square centimeter, thus permits a determination of the elemental abundance in primary cosmic rays. Specially prepared plastic materials can also be made sensitive to α particles and neutrons. Such detectors are used in the field of radiation protection for radon monitoring and neutron measurement.

3
Gas Detectors

3.1
Bethe–Bloch Energy-Loss Formula

Particles and radiation cannot be detected directly, but rather only through their interactions with matter. There are specific interactions for charged particles that are different from those of neutral particles, for example, of photons. The variety of interactions is quite rich and, as a consequence, a large number of detection devices for particles and radiation exist. The most important energy-loss mechanism for charged particles in gas detectors is the ionization loss, which can be described by the Bethe–Bloch formula, which represents the energy loss dE per length dx. It is given by Yao, 2006

$$-\frac{dE}{dx} = 4\pi N_A r_e^2 m_e c^2 z^2 \frac{Z}{A} \frac{1}{\beta^2} \left(\ln \frac{2 m_e c^2 \gamma^2 \beta^2}{I} - \beta^2 - \frac{\delta}{2} \right) \tag{1}$$

where z is the charge of the incident particle in units of the elementary charge;
Z, A are the atomic number and atomic weight of the absorber;
m_e is the electron mass;
r_e is the classical electron radius;
N_A is the Avogadro number (= number of atoms per mole);
I is the ionization constant, characteristic of the absorber material;
β is the velocity of the particle v normalized to the velocity of light c, $\beta = v/c$;
γ is the Lorentz factor, $\gamma = 1/\sqrt{1-\beta^2}$;
δ is a parameter that describes how much the extended transverse electric field of incident relativistic particles is screened by the charge density of the atomic electrons. In this way, the energy loss is reduced (“density effect,” “Fermi plateau” of the energy loss).

A useful constant appearing in the Bethe–Bloch equation is

$$4\pi N_A r_e^2 m_e c^2 = 0.3071 \, \frac{\text{MeV}}{\text{g/cm}^2} \tag{2}$$

In the low-energy domain, the energy loss decreases like $1/\beta^2$ and reaches a broad minimum of ionization near $\beta\gamma \approx 4$. Relativistic particles ($\beta \approx 1$), which have an energy loss corresponding to this minimum, are called *minimum-ionizing particles*. In light absorber materials, where the ratio $Z/A \approx 0.5$, the energy loss of minimum-ionizing particles can be roughly represented by

$$-\left.\frac{dE}{dx}\right|_{\text{min}} \approx 2 \frac{\text{MeV}}{\text{g/cm}^2} \tag{3}$$

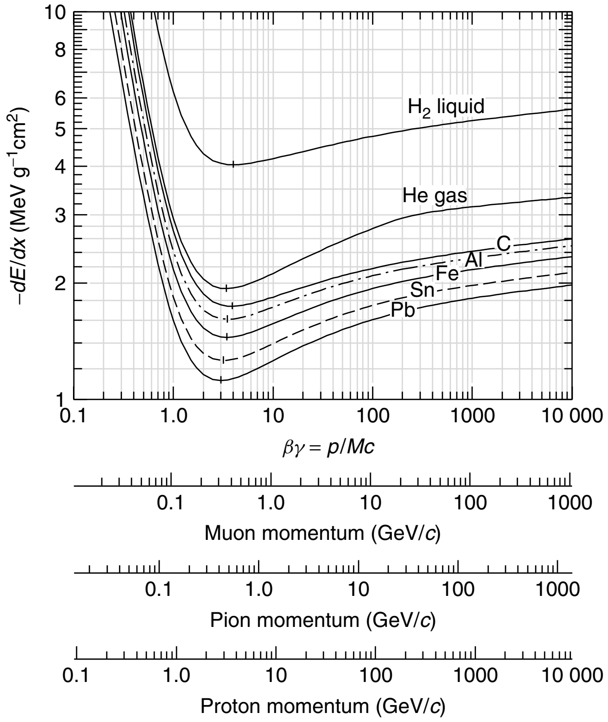

Fig. 4 Mean energy loss in liquid hydrogen, gaseous helium, carbon, aluminum, iron, tin, and lead. p is the momentum of the particle, M its mass, and c is the velocity of light; Yao, 2006.

The energy loss increases again for $\beta\gamma > 4$ ("logarithmic rise" or "relativistic rise"). The increase approximately follows a dependence like $\ln \gamma$ (see Figure 4). For thin absorbers, the ionization energy loss is subject to asymmetrical Landau fluctuations.

3.2
Ionization Yield

An interesting number for gas detectors is the ionization yield. One must distinguish between primary ionization, that is, the number of primary electron–ion pairs produced, and the total ionization. A sufficiently large amount of energy can be transferred to some primary electrons so that they also can ionize (knock-on electrons or δ rays). This secondary ionization together with the primary ionization forms the total ionization. The average energy required to form an electron–ion pair (W value) exceeds the ionization potential of the gas because inner shells of the gas atoms can also be involved in the ionization process, and a fraction of the energy of the incident particle can be dissipated by excitation processes, which do not lead to free electrons. The W value of a material is constant for relativistic particles and increases only slightly for low velocities of incident particles.

For gases, the W values are around 30 eV. They can, however, strongly depend on impurities in the gas. This number has to be compared to the average energy required for the production of an electron–hole pair in solid-state radiation detectors, which is only around 3.5 eV. Therefore, the statistical fluctuations in the number of charge carriers produced for a given energy loss is much smaller in solid-state detectors than in gaseous detectors.

3.3
Ionization Chambers

An ionization chamber is a gaseous detector that measures the amount of ionization produced by a charged particle passing through the gas volume. Neutral particles can also be detected by this device via secondary charged particles resulting from the interaction of the primary ones with electrons or nuclei. Charged particles are measured by separating the charge-carrier pairs produced by their ionization in an electric field and guiding the ionization products to the anode or cathode, respectively, where corresponding signals can be recorded. If a particle is totally absorbed in an ionization chamber, such a detector type measures its energy.

In the simplest case, an ionization chamber consists of a pair of parallel electrodes mounted in a gastight container that is filled with a gas mixture, which allows electron and ion drift. Charged particles produce electron–ion pairs along their track. The number of created charge carriers depends on the particle type and energy and on the gas.

The parallel electrodes of the ionization chamber producing a homogeneous electric field are acting as a capacitor, which is initially charged to a certain voltage. The drifting charge carriers induce an electric charge on the electrodes, which leads to certain change of the voltage, ΔU. The signal amplitude ΔU has contributions from fast-moving electrons and the slowly drifting ions. The disadvantage is that the output signal depends on where the particles enter the ionization chamber. This can be solved by introducing a Frisch grid, permitting the particles to enter the chamber only in a well-defined region.

Ionization chambers are mainly used in the spectroscopy of particles of higher charge, because, in this case, the deposited energies are, in general, larger (typically 5 MeV for α particles from radioactive sources) compared to those of singly charged minimum-ionizing particles. A minimum-ionizing particle passing a layer of 4 cm of argon will deposit only about 11 keV, which provides about 400 pairs. To detect such a small signal is a very difficult task.

Apart from planar ionization counters, cylindrical ionization counters are also in use. Because of the cylindrical arrangement of the electrodes the electric field in this case is no longer constant, but increases inversely proportional to the distance to the anode, which is usually a thin wire. The important point with cylindrical ionization chambers is that no multiplication of charge carriers occurs in the gas. Only the originally produced number of electrons and ions is collected.

3.4
Proportional Counters

In contrast to ionization chambers, the high voltage in proportional chambers is increased so that the initially produced charge carriers gain enough energy between two collisions to produce secondary electrons. In this way, an avalanche of secondary and tertiary charge carriers is started.

If N_0 primary electrons are produced, the number of particles $N(x)$ at the point x is calculated to be

$$N(x) = N_0 e^{\alpha x} \tag{4}$$

The first Townsend coefficient α depends on the field strength $\vec{E}$ and the pressure in the gas counter. The proportional range of a counter is characterized by the fact that the gas-amplification factor takes a constant value. As a consequence, the measured signal is proportional to the ionization produced. Gas-amplification factors of up to 10^6 are possible in the proportional mode. Typical gas amplifications are rather in the range between 10^4 and 10^5. At high field, collisions of electrons with atoms or molecules can cause not only ionization but also excitation. De-excitation is often followed by photon emission. However, photons produced in the course of the avalanche development are of no importance in the proportional regime.

Since the output signal in a proportional counter is proportional to the energy loss of the particle (or to the energy, if the particle stops in the counter), these radiation detectors can be used for spectroscopy, for example, of X rays or α particles.

If many anode wires are stretched in a planar chamber in parallel, one arrives at a multiwire proportional chamber (MWPC). The working principle of an MWPC is the same as that for a proportional counter. In addition to energy-proportional signals, MWPCs provide accurate track information if the wires are stretched with relatively small separations. As a contamination monitor, they can also be used in the field of radiation protection to allow the measurement of possible contaminations over larger areas.

3.5
Geiger–Müller Counters

The increase of the field strength in a proportional counter leads to a copious production of photons during the avalanche formation. As a consequence, the probability to produce further new electrons by the photoelectric effect increases. This photoelectric effect can also occur at points distant from the production of the primary avalanche. These electrons liberated by the photoelectric effect will initiate new avalanches, whereby the discharge will propagate along the anode wire, in contrast to the proportional chamber, where the discharge is localized to the point of particle passage.

The discharge is normally stopped by "quenching." In self-quenching counters, a quench gas is admixed to the counting gas, which is a noble gas in most cases. Hydrocarbons like methane (CH_4), ethane (C_2H_6), isobutane (iC_4H_{10}), alcohols like ethyl alcohol (C_2H_5OH) or methylal ($CH_2(OCH_3)_2$), or halides, like ethylbromide, are suitable as quenchers. These additions will absorb photons in the ultraviolet (UV) range (wavelength 100–200 nm), thereby reducing their range to a few wire radii (≈100 µm). The transverse propagation of the discharge proceeds only along and in the vicinity of the anode wire because of the short range of the photons. The photons have no chance to liberate electrons from the cathode by the photoelectric effect because they will be absorbed before they can reach the cathode. After a flux tube of positive ions has been formed along the anode wire, the external field is reduced by this space charge by such an amount that the avalanche development comes to an end. The positive ions drifting in the direction of the cathode will collide on their way with quench-gas molecules, thereby becoming neutralized. The molecule ions, however, have insufficient energy to liberate electrons from the cathode upon impact. Consequently, the discharge stops by itself.

3.6
Streamer Tubes

In Geiger counters, the fraction of counting gas to quenching gas is typically 90 : 10. The anode wires have diameters of 30 μm and the anode voltage is around 1 kV. If the fraction of the quenching gas is considerably increased, the lateral propagation of the discharge along the anode wire can be completely suppressed. One again obtains, as in the proportional counter, a localized discharge with the advantage of large signals (gas amplification $\geq 10^{10}$ for sufficiently high anode voltages), which can be processed without any additional preamplifiers. These streamer tubes, sometimes also called *Iarocci tubes*, are operated with "thick" anode wires between 50 μm and 100 μm. Gas mixtures with $\leq$60% argon and $\geq$40% isobutane can be used. Streamer tubes operated with pure isobutane also proved to function well.

3.7
Drift Chambers

MWPCs allow only modest spatial resolutions. For a wire spacing of only 2 mm resolutions around 500 μm are achievable. The number of anode wires required to cover large areas with MWPCs becomes prohibitive. The use of the drift chamber provides a way out of this problem. The time Δt between the moment of the particle passage through such a chamber and the arrival time of the charge cloud at the anode wire depends on the point of passage of the particle through the chamber. If v^- is the constant drift velocity of the electrons, a linear relation between the drift time and the distance to the anode wire holds. The precise measurement of this drift time allows to determine the spatial coordinate with high accuracy. The resolution is only limited by longitudinal diffusion and by primary ion statistics. Another advantage of drift chambers is that the anode-wire spacing can be much larger than in MWPCs, typically several centimeters. With an appropriate time readout, spatial resolutions under 100 μm are achievable. The drift velocity depends on the gas mixture, with typical values around several centimeters per microsecond. The consequence of this is that this detector does not permit high repetition rates. The drift chamber cannot distinguish between particles passing to the right or to the left of the readout wire. This left–right ambiguity can easily be resolved by using a double layer of chambers with staggered anode wires. In order to produce a suitable drift field, potential wires are introduced between neighboring anode wires.

Drift chambers can be made planar to cover large areas, such as muon chambers for fixed-target and collider experiments, but as vertex detectors in e^+e^- colliders often cylindrical arrangements are in use.

3.8
Time-Projection Chambers (TPCs)

The *crème de la crème* of track recording in cylindrical and planar gas detectors at the moment is realized with the time-projection chamber (TPC). Apart from the counting gas, this detector contains no other constructional elements and thereby represents the optimum as far as minimizing multiple scattering and photon conversions are concerned. The TPC is usually divided into two halves by means of a central electrode. A typical counting gas is a mixture of argon and methane (90 : 10).

The ionization produced by charged particles drifts in the electric field, in the direction of the endfaces of the chamber, which consist of MWPCs in most cases. For cylindrical chambers, the electric field is usually supplemented by a parallel magnetic field. The magnetic field suppresses the diffusion perpendicular to the field. This is achieved by the action of the magnetic forces on the drifting electrons, which, as a consequence, spiral around the direction of the magnetic field. For typical values of electric and magnetic field strengths, Larmor radii below 1 μm are obtained. The MWPCs at the endfaces determine the projected coordinates x and y. The arrival time of the ionization electrons at the endplates supplies the z coordinate along the cylinder axis. Therefore, the TPC is a truly three-dimensional imaging device (see Figure 5).

The gas amplification of the drifting ionization takes place at the anode wires of the MWPC, which are mostly stretched in azimuthal direction. To obtain accurate three-dimensional coordinates, the cathodes of the endcap-MWPC segments are usually structured as pads. The numbers of the fired wire and pad provide the coordinates x and y.

In addition, the analog signals on the anode wires give information on the specific energy loss and can consequently be used for particle identification. Typical values of the magnetic field are around 1.5 T and around 20 kV m^{-1} for the electric field. Since in most constructions

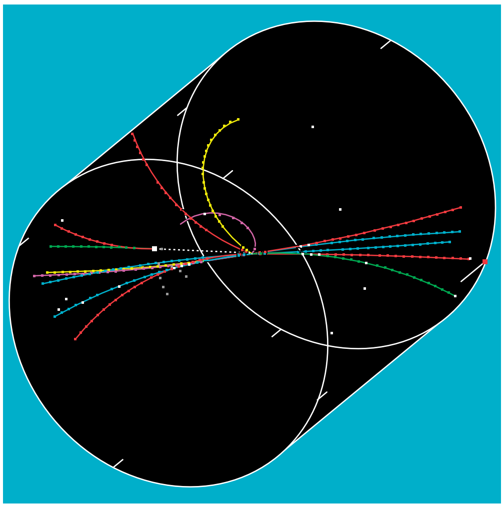

Fig. 5 Two-jet event from an electron–positron annihilation into hadrons as seen in the ALEPH time-projection chamber at the large electron–positron storage ring (LEP) at CERN; ALEPH Collaboration, 2000. Photo Credit ALEPH Collaboration; Roberto Tenchini.

electric and magnetic field are parallel, the Lorentz angle is zero and the electrons drift parallel to $\vec{E}$ and $\vec{B}$ (there is no "$\vec{E} \times \vec{B}$ effect").

However, a problem is caused by the large number of positive ions, which are produced in the gas-amplification process at the endplates and which have to drift a long way back to the central electrode. The strong space charge of the drifting positive ions would cause the field quality to deteriorate. This can be overcome by introducing an additional grid ("gate") between the drift volume and the endcap MWPC. The gate is normally closed. It is only opened for a short period of time if an external trigger signals an interesting event. In the closed state, the gate prevents ions from drifting back into the drift volume. Therefore, the quality of the electric field in the sensitive detector volume remains unchanged. This means that the gate serves a dual purpose. On the one hand, electrons from the drift volume can be prevented from entering the gas-amplification region of the endcap MWPC, if there is no trigger that would signal an interesting event. On the other hand – for interesting gas-amplified events – the positive ions are prevented from drifting back into the detector volume. TPCs can be made very large (diameter ≥ 3 m, length ≥ 5 m). They contain a large number of analog readout channels (number of anode wires $\approx$5000 and cathode pads $\approx$50 000). Several hundred energy-loss samples can be obtained per track, which ensures an excellent determination of the radius of curvature and allows an accurate measurement of the energy loss, which is essential for particle identification. The drawback of the TPC is that high particle rates cannot be handled, because the drift time of the electrons in the detector volume amounts to 40 microseconds (for a drift path of 2 m) and the readout of the analog information also requires several microseconds.

3.9
Micropattern Gaseous Detectors

The construction of MWPCs would be simplified and their stability and flexibility would be greatly enhanced if anodes were made in the form of strips or dots on insulating or semiconducting surfaces instead of stretching anode wires in the counter volume. The rate capability would improve by more than one order of magnitude for these devices because of the short drift times. At present, the class of micropattern gaseous detectors is already rather wide and many new promising devices are under study.

These microstrip gas chamber (MSGC) detectors are miniaturized MWPCs, in which the dimensions are reduced by about a factor of 10 in comparison to conventional chambers. The typical pitch is 100–200 μm and the gas gap ranges from 2 to 10 mm. This has been made possible because the electrode structures can be reduced with the help of electron lithography. The wires are replaced by strips that are evaporated onto a thin substrate. Cathode strips arranged between the anode strips allow for an improved field quality and a fast removal of positive ions. The segmentation of the otherwise planar cathodes in the form of strips or pixels also permits two-dimensional readout. Instead of mounting the electrode structures on ceramic substrates, they can also be arranged on thin plastic foils. In this way, even light, flexible detectors can be constructed, which exhibit a high spatial resolution. Possible disadvantages lie in the electrostatic charging-up of the insulating plastic structures, which can lead to time-dependent amplification properties because of the modified electric fields. The obvious advantages of these microstrip detectors – apart from their excellent spatial resolution – are the low dead time (the positive ions being produced in the avalanche will drift the very short distance to the cathode strips in the vicinity of the anodes), the reduced radiation damage (because of the smaller sensitive area per readout element), the high-rate capability, and the reduced occupancy.

Another structure providing charge multiplication is the gas electron multiplier (GEM). This is a thin ($\approx$50 μm) insulating kapton foil coated with a metal film on both sides. It contains chemically produced holes of 50–100 μm in diameter with 100–200 μm pitch. The metal films have different potentials to allow gas multiplication in the holes. A GEM-based detector contains a drift cathode separated from one or several GEM layers and an anode readout structure to read out the ionization information. The readout is then done in a similar way as in most other micropattern detectors.

3.10
Transition-Radiation Detectors (TRD)

Transition radiation is emitted when a charged particle traverses a medium with discontinuous dielectric constant. A charged particle moving toward a boundary, where the dielectric constant changes, can be considered to form together with its mirror charge an electric dipole whose field strength varies in time. The time-dependent dipole field causes the emission of electromagnetic radiation. This emission can be understood in such a way that although the dielectric displacement $\vec{D} = \varepsilon\varepsilon_0\vec{E}$ varies continuously in passing through a boundary, the electric field does not. The energy radiated from a single boundary (transition from vacuum to a medium with dielectric constant ε) is proportional to the Lorentz factor of the incident charged particle. This provides an excellent possibility to identify the nature of this particle.

Since the number of transition-radiation photons produced per boundary is rather low, usually a stack of transparent foils is employed. The generated photons – preferentially in the X-ray domain – are detected in a standard MWPC or drift chamber. It is important that the generator foils are made of low-Z material, so that they do not absorb the X-ray transition-radiation photons, and the counting gas in the MWPC is of high Z (e.g., xenon) to efficiently detect them. Transition-radiation detectors (TRDs) are mostly used for particle-identification purposes. This is related to the fact that the yield of transition-radiation photons is proportional to the Lorentz factor (i.e., energy) of the particle rather than the velocity, which saturates at high energies.

3.11
Neutron Counters

Neutrons, just as photons, can only be detected indirectly. Depending on the neutron energy, various reactions can be considered, which produce charged particles that are then detected via their ionization or scintillation in standard radiation detectors.

1. Low kinetic energies (<20 MeV)

$$
\begin{aligned}
n + {}^{6}\mathrm{Li} &\rightarrow \alpha + {}^{3}\mathrm{H} \\
n + {}^{10}\mathrm{B} &\rightarrow \alpha + {}^{7}\mathrm{Li} \\
n + {}^{3}\mathrm{He} &\rightarrow p + {}^{3}\mathrm{H} \\
n + p &\rightarrow n + p
\end{aligned}
\tag{5}
$$

   The conversion can be performed in a proportional counter with BF_3 or ^{3}He filling or a mixture with an addition of hydrocarbons, like CH_4. Also a scintillator consisting of suitable conversion material like LiI(Tl) can be used.
2. Medium energies
   ($20\ \mathrm{MeV} \leq E_{\mathrm{kin}} \leq 1\ \mathrm{GeV}$)
   The (n, p) recoil reaction can be used for neutron measurements in detectors, which contain many quasi-free protons in their sensitive volume (e.g., hydrocarbons, like, e.g., CH_4).
3. High energies ($E_{\mathrm{kin}} > 1\ \mathrm{GeV}$)
   Neutrons of high energy initiate hadron cascades in inelastic interactions, which are easy to identify in hadron calorimeters.

Neutrons are detected with relatively high efficiency at very low energies. Therefore, it is often useful to slow down neutrons with substances containing many protons (“moderation”), because neutrons can transfer a large amount of energy to collision partners of the same mass. In the field of radiation protection, it is also important to measure the neutron energy (e.g., by threshold counters), because the relative biological effectiveness depends on it.

4
Scintillators

Scintillator materials can be inorganic crystals, organic liquids or plastics, and gases. The scintillation mechanism in inorganic crystals is an effect of the lattice. Incident particles can transfer energy to the lattice by creating electron–hole pairs or taking electrons to higher energy levels below the conduction band. Recombination of electron–hole pairs may lead to the emission of light. Also, electron–hole bound states (excitons) moving through the lattice can emit light when hitting an activator center and transferring their binding energy to activator levels, which subsequently de-excite. Important parameters for inorganic scintillators are the light yield, the emission spectrum, and the decay time of the light signal. In thallium-doped NaI crystals, about 25 eV are required to produce one scintillation photon. The decay time in inorganic scintillators can be quite long (e.g., 1 microsecond in CsI(Tl)), but there are also fast scintillators like BaF_2 with a decay component of 0.7 nanoseconds. BaF_2 has its emission maximum in the UV and therefore requires quartz windows for the readout with photomultipliers. If scintillators are used as sampling elements in electromagnetic calorimeters, materials with a short radiation length X_0, like bismuth germanate (BGO: $Bi_4Ge_3O_{12}$), cadmium or lead tungstate ($CdWO_4$, $PbWO_4$), or cerium-activated lutetium oxyorthosilicate (LSO: $Lu_2SiO_5(Ce)$) are required.

In organic substances, the scintillation mechanism is different. Certain types of molecules will release a small fraction (≈3%) of the absorbed energy as optical photons. This process is especially marked in organic substances that contain aromatic rings, such as polystyrene, polyvinyltoluene, and naphthalene. Liquids that scintillate include toluene or xylene. The primary scintillation light is preferentially emitted in the UV range. The absorption length for UV photons in the scintillation material is rather short: the scintillator is not transparent for its own scintillation light. Therefore, this light is transferred to a wavelength shifter, which absorbs the UV light and reemits it at longer wavelengths (e.g., in the green). Owing to the lower concentration of the wavelength-shifter material, the reemitted light can get out of the scintillator and be detected by a photosensitive device (see Figure 6). The technique of wavelength shifting is also used to match the emitted light to the spectral sensitivity of the photomultiplier. For plastic scintillators, the primary scintillator and wavelength shifter are mixed with an organic material to form a polymerizing structure. In liquid scintillators, the two active components are mixed with an organic base.

About 100 eV are required to produce one photon in an organic scintillator. The decay time of the light signal in plastic scintillators is, in most cases, substantially shorter compared to inorganic substances (e.g., 30 nanoseconds in naphthalene and around 2–3 nanoseconds in polystyrene). Also polystyrene-based scintillators containing soluted organic compounds of heavy elements with ultrashort decay times (0.5 nanoseconds) for fast-timing purposes are available.

Gas scintillators are used in cosmic rays for extensive air-shower experiments, where the atmospheric nitrogen is used as fluorescence agent. Because of the low light absorption in gases, there is no need for wavelength shifting.

Plastic scintillators do not respond linearly to the energy-loss density. The number of photons produced by charged particles is described by Birk's semiempirical formula

$$N = N_0 \frac{dE/dx}{1 + k_B dE/dx} \tag{6}$$

where N_0 is the photon yield at low specific ionization density and k_B is

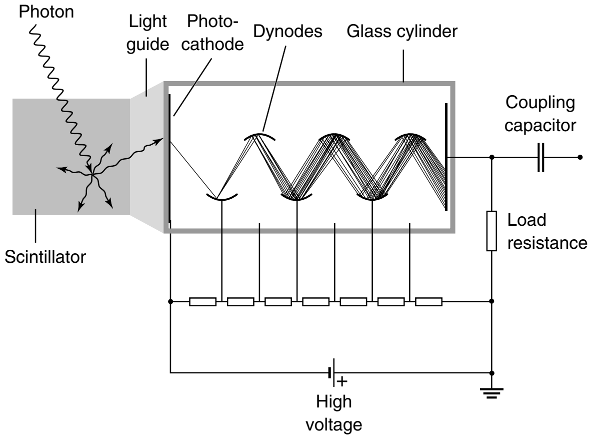

Fig. 6 Scintillation counter with photomultiplier readout; Grupen, 2008.

Birk's density parameter. For low energy losses, Equation (6) leads to a linear dependence

$$N = N_0 \cdot \frac{dE}{dx} \tag{7}$$

while for very high dE/dx saturation occurs at

$$N = \frac{N_0}{k_B} \tag{8}$$

5
Solid-State Detectors

Solid-state detectors are essentially ionization chambers with solids as a counting medium. Because of their high density compared to gaseous detectors, they can absorb particles of correspondingly higher energy. Charged particles or photons produce electron–hole pairs in a crystal. An electric field applied across the crystal allows the charge carriers produced to be collected.

The operating principle of solid-state detectors can be understood from the band model of solids. According to this theory, the electron energy levels of individual atoms or ions within a crystal are unified forming energy bands. According to the Pauli principle, each band can contain a finite number of electrons. So, some low-energy bands are fully filled with electrons while the high-energy bands are empty, at least at low temperature. The lowest partially filled or empty band is called *conduction band*, while the highest fully filled band is referred to as *valence band*. The gap between these bands is called *forbidden band* or band gap, E_g.

When the "conduction band" is partially filled, electrons can move easily under the influence of an electric field; hence, this solid is a conductor. Such a material cannot be used as an ionization counter. The solids that have basically empty conduction bands are divided conventionally into insulators (specific resistivity $10^{14}–10^{22}$ Ω cm at room temperature) and semiconductors ($10^9–10^{-2}$ Ω cm). The electric charge in these materials is carried by electrons, which have been excited to the conduction band from the valence band. The corresponding vacancies in the valence band are called *holes* and are able to drift in the electric field as well.

The common solid-state ionization counters are based on semiconductors. The specific resistivity of the material is determined as

$$\varrho = \frac{1}{e(n\mu_e + p\mu_p)} \tag{9}$$

where n and p are electron and hole concentrations, respectively, while μ_e, μ_p are their mobilities and e is the elementary charge. In a pure semiconductor the electron concentration, n, is equal to the hole concentration, p. Electron and hole concentrations in solid-state detectors are intentionally changed by special doping. A germanium or silicon crystal becomes n-conducting (i.e., conducting for negative charge carriers, electrons), when electron-donor impurities are introduced into the lattice. Germanium and silicon have four electrons in the outer shell. Atoms with five electrons in the outer shell act as electron-donor impurities. Similarly, germanium and silicon become p-conducting (i.e., conducting for holes) if trivalent atoms, which act as electron-acceptor impurities, are introduced into the crystal lattice. Phosphor and arsenic act as electron donors. The neighboring silicon (germanium) atoms can only bind four electrons. The fifth electron of the electron-donor impurity is only weakly bound and can easily reach the conduction band. The donor levels are situated approximately 0.05 eV below the edge of the conduction band. If trivalent electron-acceptor impurities like boron or indium are added to the lattice, one of the silicon bonds remains incomplete. This acceptor level, which is about 0.05 eV above the edge of the valence band, tries to attract one electron from a neighboring silicon atom. As a consequence, the state of the missing electron (the hole) migrates through the crystal. The addition of small amounts of energy can cause the holes to be transferred to the valence band, thereby causing a hole current. Lithium acts as an electron donor because it has only one weakly bound electron in the outer shell.

If a charged particle traverses an *n*- or *p*-conducting crystal, it will produce electron–hole pairs along its track. The primary electrons can produce further secondary electron pairs or excite lattice vibrations. A plasma channel is produced along the particle track with charge-carrier concentrations from 10^{15} up to $10^{17}/\mathrm{cm}^3$. The working principle of a solid-state detector now consists of collecting the free charge carriers in an external drift field before they can recombine with the holes. If this is successful, the measured charge signal is proportional to the energy loss of the particle or, if the particle deposits its total energy in the sensitive volume of the detector, it is proportional to the particle energy.

Solid-state counters can be used in nuclear physics for α, β, and γ spectroscopy. High-purity germanium detectors provide excellent energy resolution at the level of $\Delta E/E \approx 10^{-3}$ in the mega-electronvolt range (see Figure 7 and Figure 8). If the readout planes of silicon detectors are segmented into strips

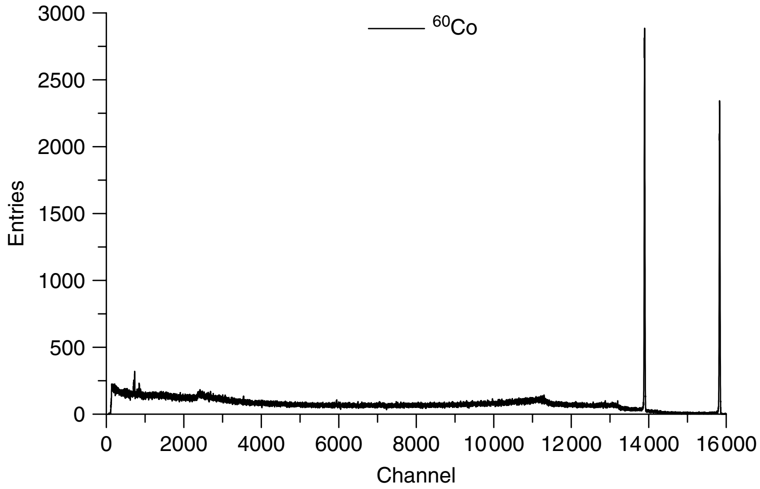

Fig. 7 γ-ray spectrum of ^{60}Co measured in a high-purity Ge detector. The energy resolution of the 1.17 MeV and 1.32 MeV γ-ray lines is rather impressive; Hausmann, 2002; private communication 2002. Photo credit Joachim Hausmann.

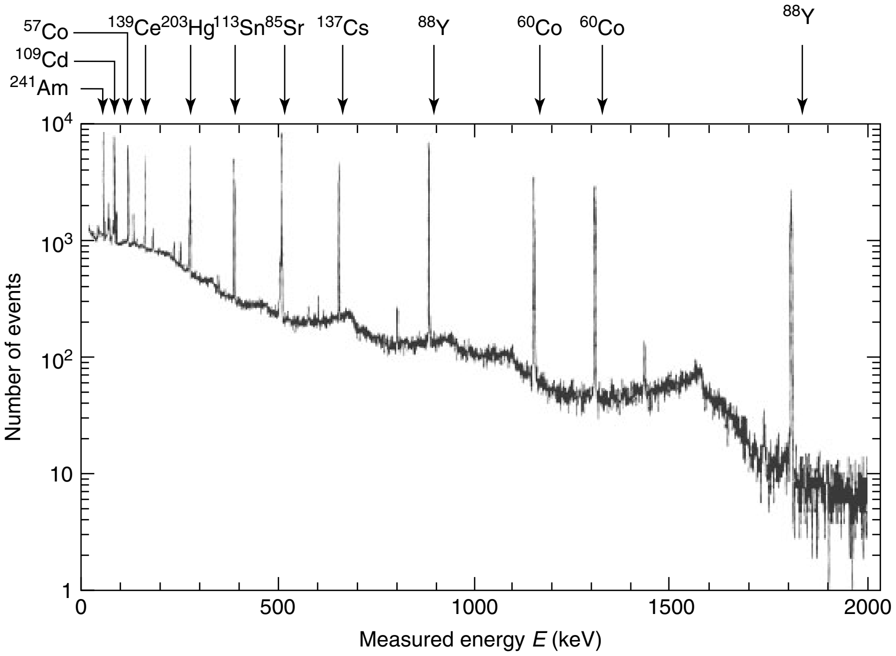

Fig. 8 Photopeak identification in a radioisotope sample using a high-purity germanium detector; Grupen, 2008.

or pixels, also outstanding spatial resolutions of about 10 μm can be achieved. This, however, requires a large number of readout channels equipped with low-noise charge-sensitive amplifiers. The number of readout elements can be reduced if, in addition, the drift time from the moment of charge generation to the arrival time of the drifting charge at the readout element is measured (silicon drift chamber).

For the operation of silicon pixel counters in harsh radiation environments, aging effects also become an issue.

Even better energy resolutions can be achieved if quantum transitions, which require less energy than ionization or electron–hole pair creation, are used. For example, phonons in solid-state materials have energies around 10^{-5} eV for temperatures of 100 mK. Other types of quasi-particles at low temperature are Cooper pairs in a superconductor, which are bound states of two electrons with opposite spin that behave like bosons. Cooper pairs in superconductors have binding energies in the range between $4 \cdot 10^{-5}$ eV (Ir) and $3 \cdot 10^{-3}$ eV (Nb). Thus, even extremely low energy depositions would produce or break up a large number of phonons or Cooper pairs. To avoid thermal excitations of these quantum processes, such radiation detectors, however, would have to be operated at extremely low temperatures, typically in the millikelvin range. For this reason, such devices are called cryogenic detectors. Cryogenic detectors can be subdivided into two main categories: first, detectors for quasi-particles in superconducting crystals, and secondly, phonon detectors in insulators. One detection method is based on the fact that the superconductivity of a substance is destroyed by the energy deposition if the detector element is sufficiently small. This is the working principle of superheated superconducting granules. The transition from the superconducting to the normal-conducting state can be detected by pick-up coils coupled to very sensitive preamplifiers or by superconducting quantum interference devices (SQUIDs). These quantum interferometers are extremely sensitive radiation detectors.

In contrast to Cooper pairs, phonons, which can be excited by energy deposition in insulators, can be detected with the methods of classical calorimetry. If ΔE is the absorbed energy, this results in a temperature rise of

$$\Delta T = \frac{\Delta E}{mc} \tag{10}$$

where c is the specific heat capacity and m is the mass of the detector. If these measurements are performed at very low temperatures, where c can be very small (the lattice contribution to the specific heat is proportional to T^3 at low temperatures), this method can be used to detect individual particles of extremely low energy.

6
Cherenkov Detectors

A charged particle, traversing a medium with refractive index n with a velocity v exceeding the velocity of light c/n in that medium, emits a characteristic electromagnetic radiation, called *Cherenkov radiation*. Cherenkov radiation is emitted because the charged particle polarizes atoms along its track so that they become electric dipoles. The time variation of the dipole field leads to the emission of electromagnetic radiation. As long as $v < c/n$, the dipoles are symmetrically arranged around the particle path, so that the dipole field integrated over all dipoles vanishes and no radiation occurs. If, however, the particle moves with $v > c/n$, the symmetry is broken resulting in a nonvanishing dipole moment, which leads to the radiation. The contribution of Cherenkov radiation to the energy loss is small compared to that from ionization and excitation even for minimum-ionizing particles. For gases with $Z \geq 7$, the energy loss by Cherenkov radiation amounts to less than 1% of the ionization loss of minimum-ionizing particles.

The angle between the emitted Cherenkov photons and the track of the charged particle can be worked out to be

$$\cos\theta_{\mathrm{C}} = \frac{1}{n\beta} \tag{11}$$

For the emission of Cherenkov radiation there is a threshold effect. Cherenkov radiation is only emitted, if $\beta > \beta_{\mathrm{C}} = \frac{1}{n}$. At threshold, Cherenkov radiation is emitted in the forward direction. The Cherenkov angle increases until it reaches a maximum for $\beta = 1$, namely,

$$\theta_{\mathrm{C}}^{\max} = \arccos\frac{1}{n} \tag{12}$$

Consequently, Cherenkov radiation is emitted only if the medium and the frequencies ν are such that $n(\nu) > 1$. The maximum emission angle, $\theta_{\mathrm{C}}^{\max}$, is small for gases ($\theta_{\mathrm{C}}^{\max} \approx 1.5^\circ$ for air) and becomes large for condensed media (about 45° for usual glass).

For fixed energy, the threshold Lorentz factor depends on the mass of the particle. Therefore, the measurement of Cherenkov radiation is suited for particle-identification purposes.

The number of Cherenkov photons emitted per path length with wavelengths between λ_1 and λ_2 is given by

$$\frac{dN}{dx} = 2\pi\alpha z^2 \int_{\lambda_1}^{\lambda_2} \left(1 - \frac{1}{n^2\beta^2}\right) \frac{d\lambda}{\lambda^2} \tag{13}$$

for $n(\lambda) > 1$, where z is the electric charge of the particle producing Cherenkov radiation and α is the fine-structure constant.

Neglecting the dispersion of the medium (i.e., n independent of λ) leads to

$$\frac{dN}{dx} = 2\pi\alpha z^2 \cdot \sin^2\theta_C \cdot \left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right) \tag{14}$$

For the optical range ($\lambda_1 = 400$ nm and $\lambda_2 = 700$ nm) one obtains for singly charged particles ($z = 1$)

$$\frac{dN}{dx} = 490 \sin^2\theta_C \,\mathrm{cm}^{-1} \tag{15}$$

All transparent materials are candidates for Cherenkov radiators. In particular, Cherenkov radiation is emitted in all scintillators and in the light guides, which are used for the readout. The scintillation light, however, is approximately 100 times more intense than the Cherenkov light. A large range of indices of refraction can be covered by the use of solid, liquid, or gaseous radiators. Even indices of refraction intermediate between solids and gas can be achieved by using transparent silica aerogels.

Cherenkov detectors are mainly used for particle identification in beams of particles of fixed momentum. Lighter particles of fixed momentum are faster than heavier ones. Therefore threshold Cherenkov counters, being sensitive to the velocity, can be adjusted to distinguish between these particles. Special imaging devices, like the ring imaging Cherenkov detector (RICH) or other differential Cherenkov counters, can also provide a direct measurement of the particle velocity.

7
Calorimeters

7.1
Electron–Photon Calorimeters

The development of cascades induced by electrons, positrons, or photons is governed by bremsstrahlung of electrons and pair production of photons. Secondary particle production continues until photons fall below the pair-production threshold, and energy losses of electrons other than bremsstrahlung start to dominate: the number of shower particles decays exponentially.

Already a very simple model can describe the main features of particle multiplication in electromagnetic cascades: a photon of energy E_0 starts the cascade by producing an e^+e^- pair after one radiation length. Assuming that the energy is shared symmetrically between the particles at each multiplication step, one gets at the depth t

$$N(t) = 2^t \tag{16}$$

particles with energy

$$E(t) = E_0 \cdot 2^{-t} \tag{17}$$

The multiplication continues until the electrons fall below the critical energy E_c,

$$E_c = E_0 \cdot 2^{-t_{\max}} \tag{18}$$

From then on, ($t > t_{\max}$) the shower particles are only absorbed. The position of the shower maximum is obtained from Equation (18),

$$t_{\max} = \frac{\ln(E_0/E_c)}{\ln 2} \approx \ln E_0 \tag{19}$$

The total number of shower particles is

$$\begin{aligned} S &= \sum_{t=0}^{t_{\max}} N(t) \\ &= \sum 2^t = 2^{t_{\max}+1} - 1 \approx 2^{t_{\max}+1} \end{aligned}$$

$$S = 2 \cdot 2^{t_{\max}} = 2 \cdot \frac{E_0}{E_c} \propto E_0 \tag{20}$$

If the shower particles are sampled in steps t measured in units of the radiation length X_0, the total number of track segments is obtained as

$$S^* = \frac{S}{t} = 2\frac{E_0}{E_c} \cdot \frac{1}{t} \tag{21}$$

which leads to an energy resolution of

$$\frac{\sigma}{E_0} = \frac{\sqrt{S^*}}{S^*} = \frac{\sqrt{t}}{\sqrt{2E_0/E_c}} \propto \frac{\sqrt{t}}{\sqrt{E_0}} \tag{22}$$

In a more realistic description, the longitudinal development of the electron shower can be approximated by

$$\frac{dE}{dt} = \text{const} \cdot t^a \cdot e^{-bt} \tag{23}$$

where a, b are fit parameters.

With homogeneous electron–photon calorimeters, energy resolutions of

$$\frac{\sigma_E}{E} = \frac{3\%}{\sqrt{E/\text{GeV}}} \tag{24}$$

can be achieved.

The lateral spread of an electromagnetic shower is mainly caused by multiple scattering. It is described by the Molière radius

$$R_M = \frac{21\ \text{MeV}}{E_c} X_0 (\text{g/cm}^2) \tag{25}$$

In a homogeneous calorimeter, 95% of the shower energy is contained in a cylinder of radius $2R_M$ around the shower axis.

Since the position of the shower maximum depends only logarithmically on the energy, electron–photon calorimeters can cover quite a large range of energies from some hundred mega electronvolts up to several hundred giga electronvolts even at moderate detector sizes. Electron–photon calorimeters are usually total-absorption devices. Such calorimeters for electrons and photons are mostly made of scintillating crystals. However, also Cherenkov media, like lead glass, can be used as converter materials.

7.2
Hadron Calorimeters

The longitudinal development of electromagnetic cascades is characterized by the radiation length X_0 and their lateral width is determined by multiple scattering. In contrast to this, hadron showers are governed in their longitudinal structure by the nuclear interaction length λ and by transverse momenta of secondary particles as far as lateral width is concerned. Since for most materials $\lambda \gg X_0$ and $\langle p_T^{\text{interaction}} \rangle \gg \langle p_T^{\text{multiple scattering}} \rangle$, hadron showers are longer and wider (see Figure 9).

Part of the energy of the incident hadron is spent on breaking up nuclear bonds. This fraction of the energy is

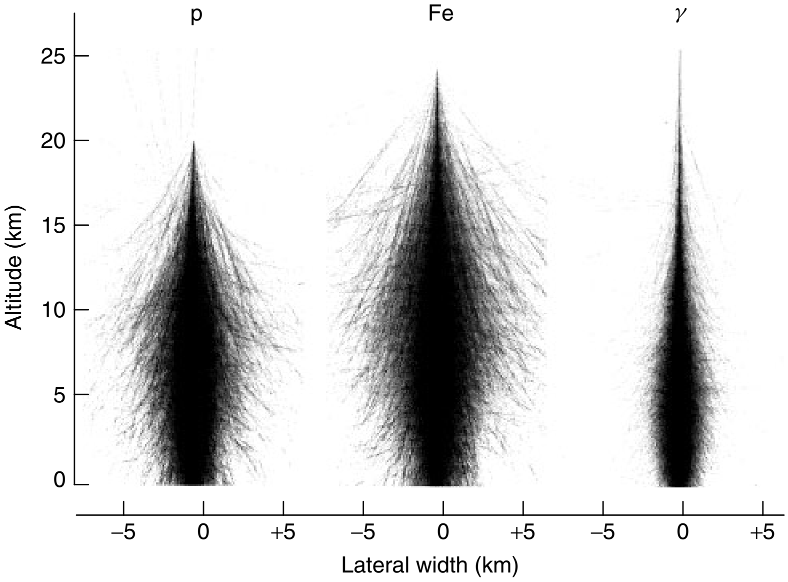

Fig. 9 Comparison between proton-, iron-, and photon-induced cascades in the atmosphere. The primary energy in each case is 10^{14} eV; Knapp and Heck, 1998. Photo credit Johannes Knapp 2007.

invisible in hadron calorimeters. Further energy is lost by escaping particles like neutrinos and muons as a result of hadron decays. Since the fraction of lost binding energy and escaping particles fluctuates considerably, the energy resolution of hadron calorimeters is systematically inferior to electron calorimeters.

Hadron calorimeters are usually sampling devices where active detector layers interspersed with passive targets collect the energy of shower particles. The active detector parts can be scintillators or liquid-argon or gaseous detectors. As passive targets mostly lead, uranium, copper, or iron is used. With a high-performance uranium–liquid-argon calorimeter energy resolutions of $\sigma_E/E = 35\%/\sqrt{E/\mathrm{GeV}}$ can be achieved.

Acknowledgments

It is a pleasure to thank Dr Tilo Stroh for a very careful reading of the chapter and his efficient help in laying out this chapter in a professional way in LaTeX.

Glossary

Acceptor: substance added as impurity to a semiconductor to create hole conductivity.

Activator: dopant used in scintillators to de-exite excitons, which then provide photons.

Aging: the performance of detectors may deteriorate in harsh radiation environments.

Avalanche Formation: if drifting electrons gain enough energy in an electric field on their mean free path, they themselves can ionize other atoms and initiate avalanche formation.

Bethe–Bloch Formula: describes the energy loss of charged particles by ionization and excitation.

Charge-Coupled Device (CCD): pixelized silicon detector, which digitizes the incident photon or particle pattern, which is then electronically read out.

Cherenkov Effect: particles with velocities v faster than light in media ($v \geq c/n$; n – index of refraction) create a characteristic electromagnetic radiation.

Critical Energy: energy at which the energy loss of electrons due to ionization and bremsstrahlung are the same.

Decay Length: track length of a short-lived particle before it decays.

Donor: substance added as impurity to a semiconductor, which can donate electrons to the conduction band.

Exciton: electron–hole bound state.

Fermi Plateau: saturation of the ionization loss at high energies due to polarization effects.

First Townsend Coefficient: characterizes the gas-amplification factor in its electric field and pressure dependence.

Frisch Grid: grid electrode in an ionization chamber, which provides signals that do not depend on the position of impact of the particles into the chamber.

Gating: by a grid in a TPC interesting events can be selected by applying suitable voltages to it.

Ionization Loss: energy loss of charged particles by transferring part of their energy to atomic electrons.

Ionization Yield: number of electron–ion pairs created by charged particles.

Knock-on Electron: atomic electron, which receives a rather large energy transfer in a collision with a charged particle (also called δ ray).

Landau Fluctuations: the energy-loss fluctuations due to the stochastic nature of the ionization process lead to asymmetric energy-loss distributions especially for thin targets.

Larmor Radius: bending radius of a charged particle gyrating in a magnetic field.

Lattice Vibrations: quantized oscillations of a lattice: phonons.

Light Yield: amount of light created in scintillators by charged particles or γ rays.

Lorentz Angle: in a combined electric and magnetic field electrons drift in the direction of $\vec{E} \times \vec{B}$.

Lorentz Factor: $\gamma = 1/\sqrt{1-\beta^2} = E/mc^2$, where $\beta = v/c$ and c is the velocity of light.

Minimum-Ionizing Particles (mips): relativistic charged particles with $\beta \cdot \gamma \approx 4$ exhibit the lowest energy loss by ionization and excitation.

Moderation: slowing down of neutrons by materials containing many quasi-free protons.

Molière Radius: characteristic size of an electromagnetic cascade describing its lateral spread.

Nuclear Interaction Length: characteristic distance between two collisions of a hadron.

Occupancy: probability that a readout element of a detector is occupied by a particle so that no further particles can be recorded on this element. High occupancy leads to dead times and inefficiency.

Pad: cathode-structure element, which enables the determination of the position of a charged particle along the wire in MWPCs.

Pitch: distance between anodes or readout structures.

Pixel: picture element as readout structure, mostly in silicon detectors.

Quenching: vapor additions to noble gases in Geiger–Müller counters limit the range of avalanche photons and cause the gas discharge to stop by itself.

Radiation Damage: degradation of the performance of detectors in a harsh radiation environment. Detectors that can be operated under such conditions are called *radiation hard* or *radiation tolerant*.

Radiation Length X_0**:** characteristic length describing the energy loss of electrons due to bremsstrahlung, $dE/dx = E/X_0$.

Relativistic Rise: rising energy loss at intermediate energies due to the relativistic deformation of the transverse electric field of fast charged particles.

RICH: ring imaging Cherenkov counter for the measurement of the velocity of charged particles.

Silica Aerogel: artificially produced Cherenkov medium of very low index of refraction consisting of a porous structure of silica and sub-micrometer air bubbles.

SQUID: superconducting quantum interference device used for the measurement of small magnetic flux changes.

Wavelength Shifter: agent that absorbs UV light and reemits visible light at lower frequency.

W Value: energy required to create an electron–ion pair in a gas or an electron–hole pair in a semiconductor.

1.1
Introduction

Toward the end of last century, when classical molecular dynamics (MD) became a very sought after technique for studying structure and conformations of large biomolecules, it was not an appropriate quest to employ and utilize quantum mechanical methods for studying dynamics of biomolecules (Warshel and Levitt, 1976; van Gunsteren *et al.*, 1983; Kollman, 1992). Initially, the potential energy surfaces were determined by fitting to experimental observed spectra (Colwell and Percival, 1983a,b), but later, also by parameterization/fitting to a combination of both experimental and theoretical data (Brooks *et al.*, 1983; Weiner *et al.*, 1984, 1986; Floris *et al.*, 1992; Brooks and Case, 1993; Cornell *et al.*, 1995; Dudek and Ponder, 1995; Maple *et al.*, 1998; MacKerell *et al.*, 1998). Owing to a limited amount of experimental data many assumptions and approximations needed to be made. These assumptions and approximations gained credence and support by being able to reproduce the (limited amount of) data. This has also created subsequent problems, as many of the assumptions and approximations involved throwing away/neglecting fundamental physics, which has subsequently been shown to be important and is essential to predict some experimental observables. In many cases, the acceptance and widespread use of simplified models and theories have prevented researchers from further developing and extending the models and theories, as it has been hard to get funding to further develop and extend methods when the general consensus in the "application" field is that the methods are already of a sufficient level to warrant general use in applications. This has subsequently immensely slowed down the development of methods, as the funding has focused on applications to the detriment of further developing the methods. The black box approach to theory becomes prevelant and then researchers are limited to what is available in the packages like Gaussian, Amsterdam Density Functional (ADF), Dalton, QChem, Turbomole, Cambridge Analytical Derivatives Package (CADPAC), Spanish Initiative for Electronic Simulations with Thousands of Atoms (SIESTA), Vienna Ab-initio Simulation Package (VASP), and so on. The development and refinement of the methods is then left to a small number of researchers who all have their so-called development versions of these codes/packages. More recently, there has

ISBN: 978-3-527-40702-6

been a call for more open-source codes, such as ABINIT, and for the National Science Foundation USA (NSF), Australian Research Council (ARC), National Institutes of Health (NIH), European Union (EU), and the National Health and Medical Research Council Australia (NHMRC) to continue to fund the development of methods for use in quantum nanobiology and molecular biology and for a core of young researchers to be supported to learn these methods by summer schools, North Atlantic Treaty Organization (NATO) workshops, and so on. This is clearly a high priority if the field is to continue to thrive and flourish and for the methods to continually be extended and developed, as problems are identified by the so-called users of the academic and commercial codes. The time lag between identifying the problems and implementing the changes/new developments needs to be reduced.

Basically, the overall goal of utilizing wave function and density functional theory based quantum mechanical methods for biomolecules is to derive from first principles functional and spectroscopic data. Here one calculates the structures, electric and magnetic properties, and vibrational, nuclear magnetic resonance (NMR), electron spin resonance (ESR), and electronic spectra of isolated molecules, aggregates, and molecular complexes in various environments where measurements have been made (nonpolar solvents, embedded within membranes, in solvents of varying polarity and ionic strengths, and finally in mixed environments, the most complex being proteins and glycoproteins that have part outside the membrane, part within the membrane, and part inside the membrane). Here one realizes that the structure, function, and properties of these complex machines are lost when the machine (molecular complex) is broken down into its various parts (individual species). Here the combination of theory and experiment has a lot to offer, as either on its own is less useful.

Within the current set of assumptions and approximations, many physically measurable properties are predicted to be "zero," which clearly shows that there are occasions and phenomena which cannot be treated by making the simplifying assumptions and approximations. The most commonly used ones being the so-called Born–Oppenheimer (BO) approximation and the harmonic approximation (both mechanical (for vibrational frequencies) and electronic (for infrared/vibrational intensities)). Actually, the concept of the potential energy surface which one parameterizes to generate a molecular mechanics force field is based on the validity of the BO approximation, which as we shall see later breaks down for some very interesting phenomena, the so-called non-BO properties. Many of these properties involve electric currents, magnetic fields, and angular momenta. The development/parameterization of classical mechanical force fields (and other molecular property surfaces which depend only on the nuclear positions of the atoms) is a field within itself, and the interested are encouraged to read speciality papers on this (Maple *et al.*, 1998; MacKerell *et al.*, 1998). The point here is that even though these molecular mechanics force fields are commonly used in molecular biology, they should be used only in specific cases where the assumptions and approximations made are valid. Clearly, for the case of quantum molecular biology, where a biological process is initiated by the absorption of a photon of light, followed by subsequent electron and energy transfer, one must go beyond the use of molecular mechanics methods. Here, one can turn to either semiempirical-based methods or first principles/*ab initio*-based methods.

The field of developing and parameterizing molecular mechanical force fields (and property surfaces) has itself benefited immensely from both wave function quantum mechanics (WFQM)- and density functional theory (DFT)-based methods, as has the field of developing semiempirical-based methods, which are based on WFQM (Klopman, 1964a,b; Dewar *et al.*, 1985; Stewart, 1989, 2007) and DFT (Elstner *et al.*, 1998; Bohr *et al.*, 1999; Frimand and Jalkanen, 2002). In addition, as more accurate and complete experimental data becomes available, these data can be used both in the parameterization and testing/verifying stages. This is especially important for more exotic molecules and molecular complexes and assemblies (nanoparticles and protein–ligand complexes to name two), which have not been included in the data sets used for parameterizing and/or testing. In many cases, for example in non *ab initio* DFT methods, this new data provides a wealth of data to test the newly developed force fields, semiempirical methods, and new exchange and correlation (XC) functionals.

Since the beginning of this century, it has seemed much more appropriate to study, mainly, the electronic structure of large molecules with the help of quantum mechanical methods, with WFQM, DFT, and Green's functions being the three most commonly used. This is because the electronic structures and properties are necessary for deriving the spectroscopic data and for understanding experimental observables (electric and magnetic properties) for the structures of molecules and molecular complexes/aggregates (Farid, 2002; Onida, Reining and Rubio, 2002; Amos, Jalkanen and Stephens, 1988; Amos *et al.*, 1987; Amos, 1982, 1986, 1984, 1987; Buckingham, 1967). Additionally, the electronic structures and properties are important for understanding the reactivity and functionality of biomolecules and biomolecular complexes (Deslongchamps, 1983; Hanessian, 1983). Hence one must extend the methods of classical MD simulations, where only one calculates the energy and gradients, to include the calculation of the various electronic and magnetic properties at each step of the MD simulation. Here, one has various ways to proceed. One can parameterize molecular property surfaces, similar to potential energy surfaces (force fields). For some properties, the property may depend on the momenta of the particles in addition to the positions (Buckingham, 1967; Amos, 1982, 1987; Buckingham, Fowler and Galwas, 1987; Lee, Colwell and Handy, 1994; Ioannnou, Colwell and Amos, 1997; Hornicek, Kapralova and Bour, 2008). The properties (observables) that depend on the momenta, in addition to the positions, are the so-called non-BO property surfaces. In some cases, there are equivalent expressions in terms of positions, momenta, and torque, which in theory should give the same results, but in practice for a variety of reasons do not (Stephens *et al.*, 1990; Amos, Jalkanen and Stephens, 1988).

Hence, the methodology and techniques which have been developed to parameterize potential energy functions can and have been extended to parameterize molecular property surfaces

(Amos, 1987). By calculating the properties at each step of the MD simulation, in addition to the energy, one can then simulate various measured properties and other experimental observables that depend on these molecular properties and how they change as a function of both positions/displacements and momenta. In addition, one would like to perturb the system and observe the system "evolve" back to equilibrium, if indeed this occurs. In some cases, the perturbation may induce conformational changes and even chemical reactions. For example, the absorption of ultraviolet (UV) radiation by DNA or RNA often involves the formation of either cyclobutane or oxetane rings, damaging the DNA or RNA. One can determine the correlated changes that occur between various quantities as the molecules and molecular complexes not only change their positions but also change their linear and angular momenta. Many of these quantities also change and are correlated with each other (this occurs due to solvation, hydration, desolvation and ligand binding, and the presence of spectator molecules like the chaperon proteins). Here, one has the ability to do correct averaging (in principle), which is harder to do when one calculates only a finite number of local minima.

Depending on the barriers between the local minima, experimental conditions such as temperature, pressure, and presence of chaperon proteins, and/or other species, which may reduce the barriers, the species and conformers present may vary (Ertl, 2008). One assumes in many cases that the system is in thermal equilibrium and that small fluctuations do not perturb the system. In some cases, the complete phase space available to the molecule or molecular complex is sampled during the experiment (assuming the barriers are low enough). Here, one assumes that the system is in thermal equilibrium and that small fluctuations do not perturb the system, and so we do not need to take them, that is, the fluctuations in temperature (pressure), into account. In other cases, one may be trapped in a local minimum as the other local minima and even the global minimum are not accessible due to larger barriers. Hence one can measure the spectra and properties of a metastable state and think that one is in the global minimum due to the stability of the spectra and hence structure which give the unique and high resolution spectra. When one then perturbs the system and gives it enough energy to surmount the large barrier, the properties can then change drastically, which is thought to be the case for instance of the prion proteins. In this case, the global minimum of the individual molecules and the complexes (dimers, trimers, etc.) are not the same. For example, on dimerization fibrils form. The vibrational circular dichroism (VCD) and Raman optical activity (ROA) spectra of fibrils have been shown to reflect a large change from the nonfibril state. These spectroscopic techniques can hence be used to monitor such processes.

In some cases, one measures a superposition of the spectra of species present weighted by their Boltzmann populations, and in other cases, one actually measures an average spectrum, which may not even represent a real species/structure, but a sort of average structure. Hence, it is important to know both what one is measuring and one is simulating, and how to connect the two experiments, one in solution and one *in silico*. One would like to determine the structure of the species present and also conformers in the case of flexible molecules from just vibrational spectral measurements, similar to what one now does with the X-ray and NMR methods. Many proteins and other molecules, molecular complexes, and molecular assemblies have escaped X-ray and NMR structure determination and it would be remarkable if vibrational structure determination were developed. To date, one can determine the percentage of secondary structure elements present and the side chain torsion angles for specific residues, but not the complete three-dimensional structure of a protein. What one would really like is to determine the side chain and backbone torsion angles for each residue. One promising extension of normal vibrational spectroscopy includes isotopic substitution at each residue in the protein to shift the modes and hence make them separate from those for the other $N-1$ residues in the protein. This allows one in many cases to assign the backbone and side chain angles for only this specific residue, but not for the other $N-1$ residues in the protein, which makes this impractical as a general method.

Finally, in addition to the ground state potential energy and property surfaces, one is interested in various excited state energy and property surfaces, and of course, the transition rates and probabilities to jump from one surface to another and back, not only in the absence of radiation but also in the presence of coherent and incoherent electromagnetic radiation (Onida, Reining and Rubio, 2002; Farid, 2002; Farid, 1999). There are many cases in biological systems where a photon (quanta) of light is necessary to initiate a/the process, hence the term *quantum nanobiology*. One example is the repair of damaged DNA (due to UV radiation) in the presence of the photolyase protein and blue light (Jalkanen *et al.*, 2006a; Bohr, Jalkanen and Malik, 2005).

In this review, we present some of our contributions to the field of quantum nanobiology and also some main contributions from other researchers to this newly developing field and the outstanding problems that are yet to be addressed to make these simulations transparent and routine. This is done modestly by complete *ab initio* calculations of small biomolecules in various environments so as to derive structures, electronic and magnetic properties, and the various spectra of these molecules, aggregates, and molecular complexes. Hence, this area of research and study is a work in progress and each year more and more work is contributing to the field's development and evolution. The development of multidimensional infrared (IR) and Raman experiments, the analogs of two- and three-dimensional NMR, have recently been proposed (Cho, 2008; Scott, 2003; Jung, 2000; Mukamel, 1995), both of which in theory give more structural information than the simple one-dimensional spectra. What has limited the development and subsequent use of these techniques has been the development of a rigorous theory. The theories used to date involve many assumptions that have not been adequately tested, verified, and substantiated (Cho, 2008). Hence there is a need for the development of a rigorous high-level first principles theory and implementation, which can be used to test and benchmark the approximate classical, semiempirical, DFT, and *ab initio* methods. This is similar to the development of commercial VCD and ROA instruments. Until rigorous theories were developed, the commercial companies were unwilling to invest in commercializing instrumentation for which the analysis of the spectra was not considered rigorous and transparent. In addition, pattern recognition methods should be developed which can be used to go directly from the measured spectra to structure or possible structures and not to have to do a complete MD, BOMD (Born Oppenheimer Molecular Dynamics) or even non-BOMD simulation for each system studied. Hence the term *vibrational structure determination* like X-ray and NMR structure determination.

In the following, we describe and summarize several applications of quantum mechanics to small biomolecules. We review our own and other groups' restricted Hartree–Fock (RHF) and DFT studies for hydrated L-alanine (LA) (Jalkanen, Bohr and Suhai, 1997; Tajkhorshid, Jalkanen and Suhai, 1998; Frimand *et al.*, 2000; Jalkanen *et al.*, 2001, 2008a; Thar, Zhan and Kirchner, 2008), L-alanyl-L-alanine (LALA) (Knapp-Mohammady *et al.*, 1999; Jalkanen *et al.*, 2003), *N*-acetyl L-alanine *N*′-methylamide (NALANMA) (Jalkanen and Suhai, 1996; Deng *et al.*, 1996; Han *et al.*, 1998; Bohr *et al.*, 1999; Pohl *et al.*, 2007; Jalkanen *et al.*, 2008a), L-histidine (LH) (Bohr and Jalkanen, 2005; Jalkanen *et al.*, 2006a; Deplazes *et al.*, 2008), *N*-acetyl L-histidine *N*′-methylamide (NALHNMA) (Bohr and Jalkanen, 2005; Jalkanen *et al.*, 2006a), L-tryptophan (LW) (Jalkanen *et al.*, 2006a; Bombasaro, Rodriquez and Enriz, 2005), and capped L-alanine L-proline L-tyrosine (APY) [*N*-acetyl L-alanine L-proline L-tyrosine *N*′-methylamide (NALALPLYNMA) (Nardi, 1999; Nardi *et al.*, 2000; Jalkanen *et al.*, 2009c)] and examine the effects of water hydration on the structures, the vibrational frequencies, vibrational absorption (VA),VCD, Raman scattering, and ROA intensities. The large changes that hydration has on the structures, relative stability of conformers, and on the VA, VCD, Raman, and ROA spectra observed experimentally are qualitatively reproduced by our DFT calculations when one adequately treats the environment, which to date has been neglected in the literature where one has mostly tried to correlate features in the vibrational spectra of proteins and peptides with known X-ray or NMR structures (Zhu *et al.*, 2005; Barron *et al.*, 2000). The goal has been to decompose the VA, VCD, Raman, and ROA spectra into their principle components, so that these principle components are the characteristic spectra of either local minima or parts of the structures of local minima, which together make up the measured spectra. This is the premise in the attempts to deconvolute or partition the measured spectra into their principle components (Kubelka, Pancoska and Keiderling, 1999; Baello, Pancoska and Keiderling, 1997; Baumruk, Pancoska and Keiderling, 1996; Keiderling, 1996).

In the past, theoreticians have neglected to properly take into account the effects of the environment on stabilizing structures that were thought to be stable without environmental influences (Jalkanen, Bohr and Suhai, 1997; Tajkhorshid, Jalkanen and Suhai, 1998; Han *et al.*, 1998; Han *et al.*, 2000; Elstner *et al.*, 2000, 2001). Many of the routinely used molecular mechanics force fields have parameterized in local minima in the absence of solvent, where these local minima are only stable in the presence of the solvent (Jalkanen *et al.*, 2008a; Han *et al.*, 1998). Hence one must be careful in using molecular mechanics force fields; cases still exist where the various force fields give different results. To be fair though, this is also the case with many of the routinely used generalized gradient approximation (GGA) and hybrid exchange correlation functionals. The methods, which have been shown to be systematically correct, are the very expensive and rigorous *ab initio* DFT and coupled-cluster methods of the Bartlett group. The methods have been used to benchmark the more approximate and computationally faster methods: GGAs, hybrid XC functionals and, of course, the SCC-DFTB (Self Consistent Charge-Density Functional Tight Binding) and PM6 (Parametric Method 6) semiempirical DFT and WFQM methods.

In addition to the work on hydration of amino acids, peptides, and proteins via vibrational spectroscopy, there is a large body of related work on gas hydrates, both experimental and theoretical (van Klaveren *et al.*, 2001). The formation of gas hydrates in natural gas pipelines initiated a lot of fundamental work on characterizing and understanding the process of hydrate formation (Hammerschmidt, 1934). Furthermore, calorimetric methods have been used to determine the compositions, heat capacities, and enthalpies of dissociation for a number of hydrates (Handa, 1986a,b). MD simulation of N_2 and O_2 hydrates have been used to interpret the double maximum in large clathrate cages and single maxima in small clathrate cages for N_2 and double maximum in both cages for O_2 (Horikawa *et al.*, 1997). Here, one is able to use MD simulations to interpret the experimentally observed spectra of gases isolated in various cages of water molecules. Similar types of experiments and MD simulations can be used to understand the hydration of amino acids, peptides, and proteins.

Neutron and X-ray diffraction experiments have shown that the water molecules encapsulating peptides and proteins are different from bulk water (Sauter *et al.*, 2001). The question of the encapsulation of polar and nonpolar groups in amino acids, peptides, and proteins and the effects of hydration on the vibrational spectra, both frequencies and VA, VCD, Raman, and ROA intensities are very much related. To date, very little work has been done on analyzing the changes of VA, VCD, Raman, and ROA intensities due to the environment. This is due to the fact that large changes are observed because of conformational changes induced by the changing environment. Here, the two effects may not be able to be distinguished. Indeed, the work of Han *et al.* (1998) on NALANMA has shown that the species of interest may not be the isolated molecule, as it is in nonpolar solvents, in the gas phase or at low temperature in inert gas matrices, but the molecule and its bound water/solvent molecules, a molecular complex. The topology of the potential energy surface of the molecule appears to be very solvent/environment dependent, a fact that has not been appreciated in the past. Much of the complexity that appears in the gas phase appears to go away in strongly interacting polar media like water. But then the question is how does one determine the species of interest/study? This is especially important and relevant when one wishes to treat the systems in layers using various levels of theory, that is, different models for each layers.

The assumption that the properties of the molecular complex are a simple superposition or sum of the properties of the individual molecules (parts) may be in gross error. Hence the continued development of fields of complex systems and systems biology. Chaos theory is another example of a theory being developed which describes phenomena which cannot be explained using the standard model.

Finally, the treatment of solvent effects on crystallization and predicting the morphology of the crystals formed has recently been addressed by Gale and Rohl (2007). They have extended the COSMO (Conductor-Like Screening Model) model to treat solute molecules in solution to deal with solute molecules in a mother liquor at the crystal surface. Here they calculate both the surface energy and attachment energy in the presence of implicit solvent (Gay and Rohl, 1995). Previous work calculated these energies from the gas phase, which, though important, are not consistent with the media from which many crystals are grown. The molecules in the mother liquor can either adsorb on various crystal faces or desorb and go back into solution. MD simulations of this process are very time consuming and Gale and Rohl have developed a method that is highly efficient and uses classical potentials. The method can be extended to *ab initio* and DFT methods, but to date this has not been done.

In addition to changes in the vibrational spectra, the thermal conductivity of gas hydrates changes; it is much lower than that of ice and has been assigned due to coupling between the guest molecules and the water framework (Tse *et al.*, 2001; Inoue, Tanaka and Nakanishi, 1996). Changes in the vibrational spectra were also simulated and are further evidence for the coupling of the modes of the crystalline water cages and the embedded guest molecules. The low frequency modes have been observed in the incoherent inelastic neutron scattering (IINS) spectra, at frequencies which are very hard to observe in the IR and Raman spectra (Gutt *et al.*, 2002). Hence it is very useful to measure the IINS spectra for molecular hydrates and complexes, in addition to the VA, VCD, Raman, and ROA spectra (Oyama *et al.*, 2003; Subramanian and Sloan, 2002).

The IINS spectra for amides have also recently been analyzed with MD simulations (Itoh *et al.*, 2003). Early simulations of the IINS spectra for *N*-methylacetamide (NMA) using simple models have been shown to be in error (Fillaux *et al.*, 1993), even though they were consistent with the experimental data (Fillaux, 1999, 2004; Kearley *et al.*, 1994, 2001; Fillaux *et al.*, 1998; Kearley, 1986, 1995; Kearley, Tomkinson and Penfold, 1987). The models for the IINS reassigned the so-called amide A N–H stretch mode in NMA to be approximately half the value found in the isolated state in nonpolar solvents and in low temperature matrices. In the solid state, the NH hydrogen is hydrogen bonded with another C=O oxygen of an adjacent NMA molecule. The model used was a double-well potential and the model fit consistently all of the IINS data, so the work was accepted and caused quite a controversy in the conventional vibrational spectroscopy field, both experimental and theoretical. Subsequent work using a more rigorous *ab initio* model has shown that the initial assignment was right and the proposed new model, although able to reproduce the experimental data, was in error (Kearley *et al.*, 1994). This was due to the approximations and assumptions being made that are not strictly valid.

This emphasizes the fact that just because a simple model is able to reproduce a limited amount of experimental data does not mean it is correct. Hence the use of Ockham's razor does not always apply (it states that essentially one should use and accept the simplest possible explanation and/or model and/or theory). In this case, the more sophisticated model was necessary to get the physics correct . In some cases, one is happy to use a nonphysical model, as is quite often used in classical molecular mechanics and MD simulations that use harmonic potentials for bond stretches. But if one wants to make predictions and understand the physics of the phenomena, then one should strive to use models and theories which include the basic physics of the problem. Hence the term *ab initio* or *first principles theories*. But in many cases even the so-called first principles or *ab initio* theories involve approximations, the one most commonly made, but not explicitly stated being the BO approximation. There are many phenomena that cannot be described within the BO approximation, for example, the electronic contribution to the atomic axial tensors (AATs), which are needed to predict/simulate the VCD intensities.

Hence it is very important that the model is used to simulate as much of the available experimental data (Serdyuk, Zaccai and Zaccai, 2007). MD simulations have recently been extended to grow methyl hydrate sII from a supersaturated aqueous methane solution (Vatamanu and Kusalik, 2008). The next application is to develop inhibitors, as hydrate formation in natural gas pipelines is very problematic and much research has been undertaken to understand and to prevent it from occurring, including the use of proteins (Zeng *et al.*, 2003; Moon, Taylor and Rodger, 2003). Here the two fields merge. The multidisciplinary nature of many problems is finally being appreciated. Here researchers can really gain from working together and getting fresh new ideas and perspectives on their problems from researchers in other fields. In many cases, having to rigorously defend one's methods and approaches, and inherent assumptions, results in one's finding some of the weaknesses that do not get noticed when one just turns the crank. It is good every once in a while to analyze the gears and mechanism that go along with the crank.

Matrix isolation (Whittle, Dows and Pimentel, 1955; Pimentel, 1975), X-ray diffraction, and solid-state vibrational studies have been undertaken to try to determine relationships between structural parameters (both intermolecular, intramolecular, and intermolecular hydrogen bonding) and vibrational frequencies (VA, VCD, Raman, and ROA intensities) (Charles and Lee, 1965; Pimentel and Charles, 1963; Pimentel and Sederholm, 1956). Early Raman studies on lysozyme, ribonuclease, and α-chymotrypsin documented that vibrational studies could also contribute information to help understand the complexities of biomolecules in aqueous solution (Lord and Yu, 1970a,b).

In addition, one has also constructed software systems such as artificial neural networks to solve the inverse scattering problem of retrieving structural information of the biomolecule from spectroscopic data, that is, vibrational frequencies as well as VA and VCD intensities of isolated NALANMA (Bohr *et al.*, 2001; Ramnarayan, Bohr and Jalkanen, 2008).

Two possible routes have been considered to predict the structure of our test molecule from the spectroscopic data. One route is to use DFT to calculate all the possible structures/conformers and their corresponding frequencies, VA, VCD, Raman and ROA intensities and then compare them to the experimental data. The other is to train expert systems, for example, neural networks on a large combination of calculated and experimental spectra with known structures, either determined experimentally from X-ray or neutron diffraction or NMR. Then correlations and/or component spectra are used to infer or extrapolate new results, that is, to predict the structures, fold classes, and percentage of secondary structural elements present from only the measured VA, VCD, Raman, and ROA spectra.

In case of large biomolecules, one can determine whether there are correlations between the best-predicted structural details from spectroscopic data and the data connected to secondary structure stability and the structures predicted from neural network programs, which are based on only sequence and structural correlations. The main problem that prevented a complete protein structure to be determined from the combined VA, VCD, Raman, and ROA spectra has been to determine which spectroscopic data are the most important determiners of secondary structures, so that such information can be used to predict secondary structural elements, and then subsequently how these secondary elements fold up to form their tertiary and finally even quaternary structure. One assumes that the information is contained in the combined VA, VCD, Raman, and ROA spectra: frequencies, line widths, and integrated intensities; polarization properties of the intensities; and finally the frequency dependence of the Raman and ROA intensities. To date the methods are only able to predict percentages of various secondary structural elements, but not to assign the secondary structural elements to each and every residue in the protein.

Finally, in addition to the secondary structural element (ϕ_i and ψ_i angles) for each residue, one needs to determine the side chain torsion angles $\{\tau_{ij}\}$ and any disulfide or salt bridges connecting two nonadjacent residues (giving extra stability to this structure). In many cases, the protein folds up to its ‘‘native state’’ and is then posttranscriptionally modified/cleaved by an enzyme to achieve its functional state. Insulin is formed from the larger proinsulin by such a process. Hence, in many cases, the functionally active state of a protein does not correspond to any one gene or protein, but to a set of proteins/genes working in a concerted manner. Hence the term *systems biology*. One cannot really understand biological function by studying individual molecules or even individual molecules in their native environment. Once must know how the molecules interact with other molecules to do so. In the case of insulin, the ligand binds to the transmembrane insulin receptor extracellularly, which triggers dimerization and then a subsequent activation of intracellular tyrosine kinase activity, the so-called signal transduction process. This is as complex as its get, and one would like to be able to use spectroscopy to follow each and every step of this very complex process.

What has made this problem more difficult for biomolecules is the absorption of radiation by the environment, water being a strong absorber in the IR, and the strong interaction between the water molecules and the biomolecules via hydrogen bonding. Hence one must consider in their native environment, the biomolecules that interact with other biomolecules, counterions, cations, anions, and finally prosthetic groups and bound ligands, which in many cases are necessary for the biomolecules to function. On ligand binding, for so-called induced fit binding, both the protein and ligand can undergo conformational changes (Keskin *et al.*, 2008). Many of the current docking algorithms assume a lock- and key-type interaction, and hence fail to predict the binding of ligands via induced fit, and hence attempts have been made to improve and extend the current docking models (Böhm and Klebe, 1996; Davis and Teague, 1999; Cavasotto and Abagyan, 2004; Oliveira *et al.*, 2006).

The use of VA, VCD, Raman, and ROA spectroscopy are ideal tools to monitor such conformational changes in both the ligand and the protein on ligand binding. In addition, VCD and optical rotation have been shown to be sensitive enough to be able to observe the induced chirality in achiral solvent molecules and ligands on binding or even interacting with a chiral environment (Losada and Xu, 2007; Jalkanen *et al.*, 2008a; Mukhopadhyay *et al.*, 2007; Losada, Tran and Xu, 2008). The sesquiterpene molecules have multiple chiral centres and in many cases flexible side chains, which though achiral, have induced chirality due to the interactions with chiral cyclic system (Jalkanen *et al.*, 2008c; Kulcitki *et al.*, 2005; Weyerstahl *et al.*, 1995; Ayafor *et al.*, 1994; Newman, 1972).

The larger goal is to find/develop/derive ways to determine structural minima, not only for the individual molecules but also when they interact to form ligand–protein complexes. In addition, in many cases there are other participants in the stable and functional biological unit, a metal center, bound solvent molecules, prosthetic groups like the porphyrin ring in myoglobin and hemoglobin, and finally, cations or anions (Sauter *et al.*, 2001). For these minimum energy stable complexes, VA, VCD, Raman, and ROA intensities are calculated by DFT in order to produce training data, that is, sets of spectroscopic data correlated with $\phi - \psi$ angles and other structural determiners for the network. Other methods such as X-ray crystallography and NMR have only been utilized to determine the native states of proteins. The VA, VCD, Raman, and ROA spectra for proteins and peptides with known structures should also be added and be part of the training set. By using DFT methods, the VA, VCD, Raman, and ROA spectra of the so-called denatured states of proteins and peptides can also be added to the training set. Many of the so-called random coil and denatured states have been shown to have a lot of secondary structure in the CD, VCD, and ROA spectra. All that one can say for sure is that these structures are different from the so-called minimum energy structures under physiological conditions. In some cases, these structures may even be global minima and the structures which are biologically active may actually be in metastable states. For example, the prion proteins may be lower in energy in the so-called denatured state, thereby making attempts to refold the prion proteins very difficult. In addition, it has recently been proposed that the functional states of some proteins are only present when the ligand is bound and the so-called native isolated protein is not one conformer (global deep minimum energy state), but an ensemble of structures (Keskin *et al.*, 2008; Sauter *et al.*, 2001). Only on ligand binding or in complex with another protein, does a single unique functional conformer arise. This could account for the failure of X-ray and NMR techniques in determining the unbound state(s)and structure(s) of this class of proteins.

One of the main problems is to determine the structures from the VA, VCD, Raman, and ROA spectra of the denatured states of proteins. Keiderling and coworkers have utilized neural network methodology to find correlations of electronic absorption (EA), electronic circular dichroism (ECD), VA, and VCD spectra with the native states of proteins by utilizing the known NMR and X-ray crystallographic structures (Pancoska, Yasui and Keiderling, 1989, 1991; Pancoska, Blazek and Keiderling, 1992; Pancoska *et al.*, 1994, 1995; Pancoska, Janota and Keiderling, 1996; Baumruk, Pancoska and Keiderling, 1996; Baello, Pancoska and Keiderling, 1997; Pancoska, Kubelka and Keiderling, 1999; Kubelka, Pancoska and Keiderling, 1999). Our work compliments their work in providing correlations of VA, VCD, Raman, and ROA spectra and the higher energy denatured states of peptides and proteins. These denatured states can be produced under various experimental conditions, that is, in aqueous solution, for example, under various pHs and salt conditions and by the presence of urea and other denaturing conditions.

In that sense one should be able to predict higher level intermediate energy states during folding processes of biomolecules with the help of expert software systems such as artificial neural networks and principle component analyses that have to be trained on known data in order to predict structural data novel to the networks. Once they are trained on known sets of intermediate energy states, that is, the set of structural data we present to the network they should be able to extrapolate to new relations between spectrum and structure. The advantage of utilizing software systems such as neural network techniques and principle component analyses for the inverse scattering problem of deriving structural information from scattering data is that they go hand in hand with experiments and DFT calculations in the sense that one of the tools can support the other when it fails or is impractical. The big endeavor is to produce detailed structural data of proteins and peptides, both in the isolated state and in complex with each other and other proteins, and either measure the experimental VA, VCD, Raman, and ROA spectra and/or simulate them with DFT calculations. In many cases the spectra and structures of proteins can be assembled from the principle components, that is, small peptides that constitute the whole protein.

In many cases, the diverse conformational spectrum of small peptides is greatly reduced when they form part of a protein. Hence one may not need to determine the structures and spectra for all possible conformers of small peptides, which itself is a very challenging problem. But like the protein not sampling all possible conformational states, peptides may and probably do not sample all possible states either. This has also been confirmed via MD simulations. Hence the many groups and researchers working on methods to sample the complete conformational space for proteins and peptides, though interesting from an academic point of view, may not really be necessary. This may be necessary to do once for each amino acid and then for sequence of dipeptide, tripeptide, and so on, but is really a waste of time and resources to do again and again for each protein and/or for each new study/simulation. What is required is to assemble/collect the results from various laboratories and annotate and verify the data before making it available to the research community. This is similar to what has been done for both experimental X-ray and NMR structures. What is needed is a similar database for theoretically determined structures. In addition, what is important for the molecular biophysicists, molecular biologists, and quantum nanobiologists to understand are the biophysical forces and interactions that are responsible for not only stabilizing the conformers, structures, and assemblies but also the biophysical processes and events which are responsible for function, and dynamics. In the opinion of these authors, too much emphasis has been put on static structures and not enough on dynamics and function. In many cases, the dynamical fluctuations and function go hand in hand. Vibrational spectroscopies are ideal techniques to study and investigate both dynamics and function.

If biomolecules and biomolecular complexes only sample a small part of the total available phase and conformational space possible, then this is what one would like to simulate, and not large portions of phase space which are not sampled and/or relevant for the experiments being studied. Part of this question can be addressed with, for example, neural network and principle component analyses tools determining the dihedral angles in the protein that are actually populated from the VA, VCD, Raman, and ROA data for each subunit. If one is able to achieve this goal, then the combination of VA, VCD, Raman, and ROA spectroscopy will take a seat along with X-ray and neutron diffraction and NMR spectroscopies as standard tools for structure determination of proteins and peptides.

A library of various conformers for each amino acid along with its corresponding properties as a function of various environments (aqueous, nonpolar membrane, or mixed) would be very beneficial, similar to the current protein data base (PDB) for X-ray and NMR-determined structures and the Cambridge crystallographic database for small molecules and ligands. Of course, along with amino acids, its corresponding capped amino acid, and sequences of dipeptides, tripeptides, and so on, data of dipeptides, tripeptides, and so on should also be collected/assembled and most certainly annotated. Many experiments and theoretical simulations have not been able to be reproduced (a fundamental part of good science) due to the lack of being adequately annotated/documented. A simple case is of whether one used distilled water or distilled *and* deionized water *and* whether one carefully controlled the pH with a buffer solution and then, which buffer, HEPES (N-2 -Hydroxyethyl-piperazine-N^1-2-Ethane-sulfonic Acid), phosphate, and so on. Some effects due to different buffering solutions have even been observed. The regrettable fact is that, in many experiments, everything seems to matter, and hence needs to be properly documented and controlled.

This large (and ever increasing) amount of data could then be used either in the parameterization and/or testing of new molecular mechanics and semiempirical methods, and even newly developed XC functionals. It is important to continually test and retest and, if necessary, reparameterize and further develop and extend methods as problems and/or disagreements arise and are found. A classical example has been the so-called standard hybrid XC functional, the B3LYP, now being replaced by a variety of more accurate and general XC functionals, one such being the B3PW91.

In the next sections, we present our theoretical approach to simulate the VA, VCD, Raman, and ROA spectra of proteins and peptides. First, we present an introduction to DFT methods. Then a presentation is given on how one calculates/simulates VA and VCD spectra followed by the same for Raman and ROA spectra. The last section covers the use of VA/VCD/Raman/ROA experimental and theoretical spectroscopy in molecular biophysics, molecular biology, and quantum nanobiology.

1.2
Introduction to Density Functional Theory methods

DFT is in principle an *ab initio* method that allows one to calculate the structures and properties of single isolated molecules and various aggregated complexes (Hohenberg and Kohn, 1964; Mermin, 1965; Kohn and Sham, 1965; Pople, 1999; Kohn, 1999; Bartlett *et al.*, 2005; Bartlett, Lotrich and Schwiegert, 2005). It is more complete than Hartree–Fock methodology in that it includes electron correlation and is better than other correlated methods because it requires less computational resources (disk, memory, and CPU time) than otherwise, for the same computational complexity. DFT formulates the energy of the system in terms of the electron density and electron current density instead of the wave function. The trade-off is that one must determine the various terms in the Hamiltonian for the total energy of the system, the kinetic energy (nuclear and electron) and Coulomb energy (nuclear–nuclear, nuclear–electron, and electron–electron)in terms of the electron density, current density, and perhaps the gradients and higher order spatial derivatives of these so-called observables. Since these quantities are themselves functions of functions, they are called functionals. Various local and nonlocal electron density functionals and local electron current density functionals have been determined and tested in their ability to determine structures, relative energies, binding energies, dipole moments, polarizabilities, hyperpolarizabilities, dipole moment derivatives, NMR shielding tensors, and various other molecular and aggregate properties (Ma and Brueckner, 1968; Rajagopal and Callaway, 1973; Perdew and Levy, 1983; Sham and Schlüter, 1985; Lannoo, Schlüter and Sham, 1985; Vignale and Rasolt, 1987, 1988; Godby, Schlüter and Sham, 1988; Becke, 1988a, 1993a; Lee, Yang and Parr, 1988; Levine and Allan, 1989; Papai *et al.*, 1990; Perdew and Wang, 1992; Malkin, Malkina and Salahub, 1993a,b; Komornicki and Fitzgerald, 1993; Colwell *et al.*, 1993; Lee and Sosa, 1994; Johnson and Frisch, 1994; Schreckenback and Ziegler, 1995; Malkin *et al.*, 1995; Wilson, Amos and Handy, 1999; Wolff, 2005; Kongsted and Ruud, 2008).

The first Hohenberg–Kohn theorem showed that the electron density determines the energy and hence reformulated the basic equation to solve as one in which one has to determine the electron density rather than the wave function (Hohenberg and Kohn, 1964). The energy function can be written as

$$E_v[\rho] = T[\rho] + V_{\mathrm{ne}}[\rho] + V_{\mathrm{ee}}[\rho] \qquad (1)$$

$$= \int \rho(\mathbf{r})v(\mathbf{r})d\mathbf{r} + F_{\mathrm{HK}}[\rho] \qquad (2)$$

where

$$F_{\mathrm{HK}}[\rho] = T[\rho] + V_{\mathrm{ee}}[\rho] \qquad (3)$$

and $v(\mathbf{r})$ is the external potential.

The second Hohenberg–Kohn theorem provides the energy variational principle, which enables one to find the density that minimizes this energy functional (Kohn and Sham, 1965). The problem is we do not know the functional $F_{\mathrm{HK}}[\rho]$ and many functionals have been developed that try to address this problem. By introducing the Kohn–Sham orbitals, Kohn and Sham were able to address the problem of not being able to determine the electron kinetic energy functional in terms of only the density. At this point, they could have also used the Kohn–Sham orbitals to determine the exchange energy functional by simply substituting now the Kohn–Sham orbitals within a Slater determinant. But by doing this, they would have introduced a nonlocal exchange term and the simplicity and robustness of DFT would not have been apparent. So instead of taking this route, which would have been to search for the correlation energy functional also in terms of the Kohn–Sham orbitals, Kohn and Sham explored using the local density approximation (LDA) for both the exchange and correlation energy functionals. For problems in solid-state physics, LDA works well and has been used for decades now. Owing to problems with scaling in WFQM, quantum chemists turned to DFT as an alternative to the WFQM semiempirical based methods. For some problems LDA did fine, but for complex organic and bioorganic molecules, especially those involving hydrogen bonding, one requires higher accuracy than LDA can give. This led to the development of the so-called GGA functionals, where in addition to the density, the exchange and correlation energy functionals are functions of the gradient of the density, in addition to the density (Perdew, Burke and Ernyerhoh, 1996, 1997). Still higher accuracy was required, and to get this higher accuracy one went to the nonlocal Hartree–Fock form for the exchange energy functional, substituting the Kohn–Sham orbitals into the expressions instead of the Hartree–Fock orbitals. This led to the so-called hybrid XC functionals.

Commonly used hybrid functionals, the Becke 3LYP (B3LYP) (Becke, 1988a, 1993a; Lee, Yang and Parr, 1988; Perdew and Wang, 1992),

$$E[\rho(x, y, z), \nabla(\rho(x, y, z))] = E_{\mathrm{RB}} + E_{\mathrm{HF}} - E_{\mathrm{LYP}} \qquad (4)$$

and Becke 3PW91 (B3PW91)

$$E[\rho(x, y, z), \nabla(\rho(x, y, z))] = E_{\mathrm{RB}} + E_{\mathrm{HF}} - E_{\mathrm{PW91}} \qquad (5)$$

hybrid exchange correlation functionals have been implemented in CADPAC, Dalton, Turbomole, and Gaussian 94, 98 and 2003 (Stephens *et al.*, 1994; Lee and Sosa, 1994; Becke, 1993a; Lee, Yang and Parr, 1988). B3LYP and B3PW91 level analytical Hessian and atomic polar tensors (APT) calculations have also been implemented in Gaussian 94, 98, 03, CADPAC, and Dalton. More recently, the AAT have been implemented in the ADF suite of programs utilizing Slater-type orbitals (STOs) (Nicu *et al.*, 2008). Previous implementations had all been with the Gaussian-type orbitals (GTOs), which have been used by quantum chemists, since these allow one to analytically evaluate many integrals, in contrast to the use of numerical integrations to evaluate many of the integrals when using STOs. But with the use of numerical integration to evaluate many of the exchange and correlation integrals required for various XC functionals, the necessity and advantage of using strictly GTOs no longer exists, and hence the return to the use of STOs.

The B3LYP and B3PW91 level force fields have been shown to be more accurate than RHF level Hessians, which must be scaled to get good agreement with both experimental frequencies and VA and VCD intensities (Jalkanen and Stephens, 1991; Stephens *et al.*, 1994; Jalkanen and Suhai, 1996; Jalkanen *et al.*, 2008a,b; Deplazes *et al.*, 2008). The nature of the normal modes have been shown to depend very much on the scaling scheme one chooses to scale the Hessian (Jalkanen *et al.*, 1987, 2008b; Jalkanen and Stephens, 1991). The advantage of the B3LYP and B3PW91 hybrid exchange correlation functionals is that the Hessians appear to be accurate enough to predict the VA and VCD intensities when coupled with accurate APT and distributed origin (DO) gauge and gauge invariant atomic orbital (GIAO) AAT without scaling. The number of molecules for which the B3LYP and B3PW91 Hessians, APT and AAT, have been calculated and used to predict and help interpret the VA and VCD spectra has been quite extensive now. This level of field has became the standard where either B3LYP or B3PW91 are able to predict the correct structure (conformer) and relative energies. The good agreement shown to date has included only a small number of functional groups and the comparison has been with measurements of the VA and VCD spectra of molecules in nonpolar solvents. Recently, systematic errors with B3LYP have been found (Matsuda, Wilson and Xiong, 2006), and hence the need for a more systematic approach to develop XC functionals. The *ab initio* DFT method of Bartlett, which uses optimized effective potentials (OEPs) for both exchange and correlation (XC), appears to be the most promising (Bartlett *et al.*, 2005; Bartlett, Lotrich and Schwiegert, 2005). The work of Bartlett built on previous works with OEPS is covered briefly and cited in the classical quantum chemistry text by Levine (2000).

Even though much more expensive than the GGAs like PBE, OEPs give the correct answer for the correct reasons (correct physics and chemistry), and hence the additional effort and cost is justified. Therefore, the OEP XC functionals of the Bartlett group have become the new gold standard and, all the more, simple, approximate, and robust XC functionals should be tested and benchmarked against the Bartlett OEPs. With the work of Bartlett and coworkers, DFT has now been put on as a rigorous level as WFQM, with a systematic way to improve both the XC functionals achievable, though at much higher cost and complexity than originally formulated first by Thomas, then Thomas and Fermi, and finally by Hohenberg, Kohn, and Sham. The merging and integration of the works by Kohn and Pople and many others in DFT and WFQM appears to have finally been achieved. Now one can use DFT and WFQM and semiempirical methods based on each almost interchangeably, depending on the focus of one's work. Each method, as well as Greens functions-based methods, has its advantages and disadvantages, especially with respect to the treatment of excited electronic states and excited state potential energy surfaces, which are required for photon-induced photochemical reactions. Many reactions in molecular biology and molecular biophysics are photon initiated, so there is plenty of work to be done to further develop and refine DFT-based methods for electronic excited state MD. In this realm, WFQM and Greens functions-based methods are more accurate and should be used to test and benchmark the time-dependent density functional theory (TD-DFT)- based methods (Onida, Reining and Rubio, 2002; Reining *et al.*, 2002; Ismail-Beigi and Louie, 2003; Zhukov, Chulkov and Echenique, 2004).

In this review, we summarize previous works and present some new results on some small peptides (LALA, NALANMA, and NALHNMA) and two amino acids (LA and LH). LA and LH are two clear examples of a biological molecules whose properties and structures in water and gas phase are very different. We have found that without the water being explicitly or implicitly accounted for, the gas phase or isolated molecule calculations are of questionable use in analyzing the measurements on these molecules in aqueous solution, though they have found recent application in mass spectroscopic studies (Ipolyi *et al.*, 2006). The zwitterionic structure of LA, the predominant species in aqueous solution, is not stable in the gas phase according to our 6-31G* B3LYP *ab initio* calculations (Jalkanen, Bohr and Suhai, 1997; Tajkhorshid, Jalkanen and Suhai, 1998). Therefore we have explicitly included solvent, in this case water, to stabilize this structure and also to be able to compare to the measurements of the VA, VCD, Raman, and ROA spectra of LA in aqueous solution (Tajkhorshid, Jalkanen and Suhai, 1998; Frimand *et al.*, 2000; Jalkanen *et al.*, 2001, 2008a). The VA and VCD spectra of LA in aqueous solution were initially measured by the groups of M. Diem at Hunter College in NY, NY (Diem, 1988) and L. Nafie at Syracuse University in Syracuse, NY (Freedman *et al.*, 1988). Raman and ROA measurements and calculations on LA have also been reported by Barron and coworkers (Barron *et al.*, 1991a). At our *ab initio* 6-31G* B3LYP DFT-optimized geometries we have calculated the vibrational frequencies, VA and VCD intensities. The VA and VCD spectra were calculated with the 6-31G* B3LYP force field (Hessian) and APT and the 6-31G** RHF DO gauge AAT.

For LALA, three zwitterionic structures were able to be stabilized with four, six, and seven water molecules, respectively (Jalkanen, Bohr and Suhai, 1997; Bohr and Jalkanen, 1998). The zwitterionic structure was not stable relative to proton transfer of one of the protons of the NH_3^+ group to the C=O group of the adjacent amide group, whereas the proton of the N−H group was concurrently transferred to the closest oxygen of the CO_2^- group. Subsequently completely solvated (hydrated) structures of the LALA zwitterion were extracted from MD simulations and subsequently optimized at the B3LYP level of theory (Knapp-Mohammady *et al.*, 1999). Here only the water molecules directly hydrogen bonded with the polar groups were kept and the number of waters varied from 10 to 14, depending on the conformation of the LALA zwitterion. In a subsequent study, we used one of the structures and predicted the VA, VCD, Raman, and ROA spectra (Jalkanen *et al.*, 2003). Here we present our new results for the LALA plus 11 water clusters embedded within the polarizable continuum model (PCM). We present the VA, VCD, Raman, and ROA spectra for the LALA zwitterion with 11 water molecules. As one can see the water absorption masks many of the LALA modes. Note that in addition to masking the LALA modes, the water modes couple with the LALA modes and therefore the water molecules in the first solvation shell surrounding the LALA zwitterion are different than those in bulk water. This has been documented by X-ray and neutron diffraction studies as well as from VCD signals due to chiral water molecules (the chirality is due to the chiral environment of the LALA molecule) (Sauter *et al.*, 2001; Losada and Xu, 2007; Losada, Tran and Xu, 2008).

The goal there was and here is to determine the structure (a conformer) of the zwitterionic form of LALA in aqueous solution from the experimental vibrational spectra, VA, VCD, Raman, and ROA, if possible. As shown by our calculations on the neutral species, there are many possible conformers for this molecule and the structure(s) of this molecule in water has(have) not yet been determined, though the VA, VCD, Raman, and ROA spectra have been measured. The goal of our work is to help answer the question of the conformation and species of LALA in aqueous solution and to develop and document a methodology which will work for larger peptides and even proteins in both native and nonnative conditions.

We also present here optimized structures of NALANMA with four waters starting from our 6-31G* B3LYP optimized structures. The relative energies of these complexes are compared with the isolated molecule values. In addition we explore the effect of changing the hybrid exchange correlation functional, as recently the B3LYP hybrid exchange correlation functional has been called into question. Hence we have replaced the LYP correlation functional with the PW91 correlation functional and have optimized the structure of NALANMA with the four bound waters embedded within the PCM and conductor-like polarizable continnum model (CPCM) continuum solvent models with the B3PW91 hybrid exchange correlation functional (Jalkanen *et al.*, 2008a).

The goal here has been to model biomolecules by explicitly adding water molecules to provide calculations which can be used to critically evaluate solvent models and specific models developed for water (liquid simulations) (Jorgensen, Madura and Swenson, 1984; Jorgensen and Swenson, 1985a,b; Jorgensen and Tirado-Rives, 1988; Jorgensen, Maxwell and Tirado-Rives, 1996). The H-bonding properties as exemplified by some of the simple water models are clearly incorrect, and we feel that conclusions based on these models can be critically evaluated utilizing the better models of water (Berendsen *et al.*, 1981). In addition, the properties for the water potentials that are used in parameterization may not necessarily be those one is interested in. For models which do not include effects due to polarization, there is no change in the electronic charge density on hydrogen bonding, which is known to occur. Hence whenever one uses a classical potential, it should be benchmarked for the properties of interest. In many cases, a more refined model must be used for more sophisticated and elaborate experiments, for example, the vibrational and EA and CD spectra. In addition, since many models using parameters reduce the error between measured and simulated results, care must be taken to ensure that the parameters do not appear to correct the physics and chemistry that is *lacking* in the model. For example, to use parameters to "make" harmonic frequencies anharmonic. By doing so, other real anharmonic effects are lost.

Various models have been developed for implicitly and explicitly taking into account water at various levels (Onsager, 1936; Richmond, 1984; Wesson and Eisenberg, 1992; Schiffer *et al.*, 1992; Fortunelli and Tomasi, 1994; Schmidt and Fine, 1994; Tomasi and Persico, 1994; Fortunelli, 1996; Cossi *et al.*, 1996; Tawa *et al.*, 1996; Ösapay *et al.*, 1996; Craw *et al.*, 1996; Rauhut *et al.*, 1996; Mok, Nwumann and Handy, 1996; Jalkanen and Suhai, 1996, 1998; Jorgensen, Maxwell and Tirado-Rives, 1996; Tajkhorshid, Han *et al.*, 1998; Knapp-Mohammady *et al.*, 1999; Frimand *et al.*, 2000; Jalkanen *et al.*, 2001, 2003, 2006a; Tomasi, Mennucci and Cammi, 2005; Mantz *et al.*, 2006). At the molecular mechanics level, the force field can be parameterized against experimental data measured on the molecule in the aqueous solution. The force field is then an effective force field in that it is not useful for doing calculations on the molecule in the gas phase or for other solvents, the optimized potentials for liquid simulation (OPLS) force field being the most specific of this type (Jorgensen, Madura and Swenson, 1984; Jorgensen and Swenson, 1985a,b; Jorgensen and Tirado-Rives, 1988; Jorgensen, Maxwell and Tirado-Rives, 1996). Another approach to the solvent and/or hydration problem is to use a distance-dependent dielectric or some other perturbation to the gas phase potential energy surface and/or interactions to take into account the effect of water without actually adding explicit waters. The goal here is to save computational time and resources because the addition of explicit water molecules adds to the length of the calculation and the multiple minimum questions become exponentially worse when one tries to find the "global minimum" of the molecule solvated by water molecules. Finally the question of temperature, and hence entropic effects are very important when modelling hydrated systems, as there are many possible orientations of the water molecules encapsulating and/or hydrating the molecule.

The hydrated structures presented here for LA, NALANMA, LALA, LH, and NALHNMA can be used to test the various water models before one uses them in expensive molecular dynamic simulations on proteins and nucleic acids. The work is a part of our collaborative work involving groups at the German Cancer Research Center, the Technical University of Denmark, Helsinki University of Technology, Curtin University of Technology, and the University of Bremen to model proteins and nucleic acids along with various ligands in the presence of water and denaturing environments. In the next sections, we present the methodology to simulate the vibrational spectrum, not only the frequencies but also the intensities, followed by the use of the spectroscopic methods in molecular biology, molecular biophysics, and quantum nanobiology.

1.3
Calculating Vibrational Absorption and Vibrational Circular Dichroism Spectra

1.3.1
Vibrational Absorption (VA) or Infrared (IR) Absorption and Vibrational Circular Dichroism

Vibrational absorption and CD spectra are related to molecular dipole and rotational strengths via,

$$\varepsilon(\bar{\nu})=\frac{8\pi^3 N_A}{3000hc(2.303)}\sum_i \bar{\nu} D_i f_i(\bar{\nu}_i,\bar{\nu}) \tag{6}$$

$$\Delta\varepsilon(\bar{\nu})=\frac{32\pi^3 N}{3000hc(2.303)}\sum_i \bar{\nu} R_i f_i(\bar{\nu}_i,\bar{\nu})$$

where ε and $\Delta\varepsilon = \varepsilon_L - \varepsilon_R$ are molar extinction and differential extinction coefficients, respectively, D_i and R_i are the dipole and rotational strengths of the ith transition of wavenumbers $\bar{\nu}_i$ in cm^{-1}, and $f(\bar{\nu}_i,\bar{\nu})$ is a normalized line-shape function and N_A is Avogadro's number. For a fundamental (0 → 1) transition involving the ith normal mode within the harmonic approximation

$$D_i=\left(\frac{\hbar}{2\omega_i}\right)\sum_\beta\left\{\sum_{\lambda\alpha}S_{\lambda\alpha,i}P^\lambda_{\alpha\beta}\right\}\times\left\{\sum_{\lambda'\alpha'}S_{\lambda'\alpha',i}P^{\lambda'}_{\alpha'\beta}\right\} \tag{7}$$

$$R_i=\hbar^2\,\mathrm{Im}\sum_\beta\left\{\sum_{\lambda\alpha}S_{\lambda\alpha,i}P^\lambda_{\alpha\beta}\right\}\times\left\{\sum_{\lambda'\alpha'}S_{\lambda'\alpha',i}M^{\lambda'}_{\alpha'\beta}\right\}$$

where $\hbar\omega_i$ is the energy of the ith normal mode, the $S_{\lambda\alpha,i}$ matrix interrelates normal coordinates Q_i to Cartesian displacement coordinates $X_{\lambda\alpha}$, where λ specifies a nucleus and $\alpha = x$, y, or z:

$$X_{\lambda\alpha}=\sum_i S_{\lambda\alpha,i}Q_i \tag{8}$$

$P^\lambda_{\alpha\beta}$ and $M^\lambda_{\alpha\beta}$ (α, $\beta = x, y, z$) are the APT and AAT of nucleus λ. $P^\lambda_{\alpha\beta}$ is defined by

$$P^\lambda_{\alpha\beta}=\left\{\frac{\partial}{\partial X_{\lambda\alpha}}\langle\psi_G(\mathbf{R})|(\mu_{\text{el}})_\beta|\psi_G(\mathbf{R})\rangle\right\}_{\mathbf{R}_o} \tag{9}$$

$$=2\left\langle\left(\frac{\partial\psi_G(\mathbf{R})}{\partial X_{\lambda\alpha}}\right)_{\mathbf{R}_o}\middle|\left(\mu^e_{\text{el}}\right)_\beta\middle|\psi_G(\mathbf{R}_o)\right\rangle + Z_\lambda e\delta_{\alpha\beta}$$

where $\psi_G(\mathbf{R})$ is the electronic wavefunction of the ground state G, $\mathbf{R}$ specifies nuclear coordinates, $\mathbf{R}_o$ specifies the equilibrium geometry, $\boldsymbol{\mu}_{\text{el}}$ is the electric dipole moment operator, $\bar{\mu}^e_{\text{el}} = -e\sum_i \mathbf{r}_i$ is the electronic contribution to $\bar{\mu}_{\text{el}}$, and $Z_\lambda e$ is the charge on nucleus λ and $M^\lambda_{\alpha\beta}$ is given by

$$M^\lambda_{\alpha\beta}=I^\lambda_{\alpha\beta}+\frac{\mathrm{i}}{4\hbar c}\sum_\gamma\varepsilon_{\alpha\beta\gamma}R^o_{\lambda\gamma}(Z_\lambda e)$$

$$I^\lambda_{\alpha\beta}=\left\langle\left(\frac{\partial\psi_G(\mathbf{R})}{\partial X_{\lambda\alpha}}\right)_{\mathbf{R}_e}\middle|\left(\frac{\partial\psi_G(\mathbf{R}_e,B_\beta)}{\partial B_\beta}\right)_{B_\beta=0}\right\rangle \tag{10}$$

where $\psi_G(\mathbf{R}_o, B_\beta)$ is the ground state electronic wavefunction in the equilibrium structure $\mathbf{R}_e$ in the presence of the perturbation $-(\mu^e_{\mathrm{mag}})_\beta B_\beta$, where $\boldsymbol{\mu}^e_{\mathrm{mag}}$ is the electronic contribution to the magnetic dipole moment operator. $M^\lambda_{\alpha\beta}$ is origin dependent. Its origin dependence is given by

$$(M^\lambda_{\alpha\beta})^0 = (M^\lambda_{\alpha\beta})^{0'} + \frac{\mathrm{i}}{4\hbar c}\sum_{\gamma\delta} \varepsilon_{\beta\gamma\delta} Y^\lambda_\gamma P^\lambda_{\delta\alpha} \tag{11}$$

where $\mathbf{Y}^\lambda$ is the vector from O to O′ for the tensor of nucleus λ. Equation (11) permits alternative gauges in the calculation of the set of $(M^\lambda_{\alpha\beta})^0$ tensors. If $\mathbf{Y}^\lambda = 0$, and hence $\mathrm{O} = \mathrm{O}'$, for all λ the gauge is termed the *common origin (CO) gauge*. If $\mathbf{Y}^\lambda = \mathbf{R}^o_\lambda$, so that in the calculation of $(M^\lambda_{\alpha\beta})^0$ O′ is placed at the equilibrium position of nucleus λ, the gauge is termed the *DO gauge* (Stephens, 1985, 1987; Buckingham, Fowler and Galwas, 1987; Amos *et al.*, 1987; Amos, Jalkanen and Stephens, 1988).

The problem with the expressions for the APT and AAT presented initially is that they involved the wavefunction and wavefunction derivatives (usually calculated with Coupled Hartree–Fock theory). These expressions were implemented in CADPAC to calculate the APT at the self-consistent field (SCF) and MP2 levels and the AAT at the SCF level. The first rigorous VA and VCD spectral simulations were performed using the Gaussian and CADPAC programs (Stephens and Lowe, 1985; Amos *et al.*, 1987; Amos, Jalkanen and Stephens, 1988, 1991). The scaled quantum mechanical (SQM) force fields (Lowe *et al.*, 1986; Jalkanen *et al.*, 1987, 1988; Kawiecki *et al.*, 1991) were initially scaled using the scaling methods of Blom and Altona (1976) and Pulay *et al.* (1979). Later more accurate MP2 force fields appeared to be accurate enough, when combined with MP2 APT and RHF/SCF AAT tensors (Stephens *et al.*, 1993). This gave qualitative accuracy in general, and in some cases even quantitative accuracy, though there were cases which were problematic, one being *trans*-1,2-dicyanocyclopropane, which is now still considered problematic and a good test case for any new method (Jalkanen *et al.*, 2008b). Subsequently, the AAT have been implemented with GIAOs at both the SCF and multiconfiguration self-consistent field (MCSCF) levels of theory within the Dalton suite of programs (Bak *et al.*, 1993, 1994, 1995).

The advantages of DFT are numerous, but the main one is to extend rigorous methodology to the calculation of properties of large biological molecules. DFT seems to provide a way to do that. But the expressions must be reformulated as expressions amenable for DFT, where one has the density expressed in terms of the so-called Kohn–Sham orbitals and not in terms of rigorous wave functions. The Kohn–Sham orbitals are only used to generate the density, and one must be very careful in applying and using the orbitals and eigenvalues outside the scope for which they were intended.

The calculation of the DFT AATs has been implemented within the coupled perturbed Kohn–Sham formalism using GTOs in CADPAC, Dalton, and Gaussian (Cheesman *et al.*, 1996) and using STOs in the ADF program (Nicu *et al.*, 2008; Wolff, 2005; te Velde *et al.*, 2001). For many cases, SCF AAT appear to be of sufficient accuracy, but with the prevalence of implementations of DFT, DFT methodology appears to be taking over. A comparison of rotational strengths for molecules with both RHF and DFT AAT is still important, as in many cases one can use a different method for the tensors required for the VA and VCD (and also Raman and ROA) intensities, than one requires for the geometry optimization and subsequent Hessian and normal mode calculation. The implementation of VA and VCD spectral simulation in Gaussian, Dalton, CADPAC, and ADF all allow one to accurately predict the VA and VCD spectra for molecules in nonpolar solvents, in inert low temperature nobel gas and N_2 matrices, and in membranes where there is no strong interaction between the solute molecule and the solvent/environment.

Recently, various continuum models have been implemented in Gaussian, Dalton, and ADF that allow not only geometry optimizations but also analytical derivative methods for the calculation of the Hessian, APT and AAT, required to simulate the VA and VCD spectra. The continuum solvent models have required continuous refinements and extensions as one has started to use them to treat biolological systems, where many of the assumptions inherent in the development of the models break down. One of these is that there are no specific directional effects which must be treated. Hydrogen bonding effects have been shown to be inadequately treated, and hybrid models have been developed to treat these systems (Jalkanen and Suhai, 1996, 1998; Jalkanen, Bohr and Suhai, 1997; Han *et al.*, 1998; Tajkhorshid, Jalkanen and Suhai, 1998; Knapp-Mohammady *et al.*, 1999; Jalkanen *et al.*, 2008a). Especially when one attempts to treat hydrogen-bonded systems with implicit solvent models one must be very careful. One cannot treat an explicit directional and specific interaction between the charged NH_3^+ and CO_2^- groups in an amino acid, peptide and protein with solvent/water molecules, cations, or anions with an implicit continuum solvent model. Here we have introduced our embedded molecular (hydrogen-bonded) complex model (Jalkanen and Suhai, 1996; Jalkanen, Bohr and Suhai, 1997; Han *et al.*, 1998; Tajkhorshid, Jalkanen and Suhai, 1998; Knapp-Mohammady *et al.*, 1999; Jalkanen *et al.*, 2006a, 2008a; Jürgensen and Jalkanen, 2006). Here one needs to identify the important solvent molecules, cations, and anions which are (thought to be) important in stabilizing the structure/conformation/functional state of the molecule/molecular complex/assembly/aggregate. This complex/assembly/aggregate can be embedded within a solvent cavity and/or protein active site and/or micelle, where the cavity surface is treated implicitly by using a lower level of theory (perhaps using a molecular mechanics force field). A complete review of these methods is beyond the scope of this work on the use of vibrational spectroscopic methods in quantum nanobiology, molecular biology, and molecular biophysics.

1.4
Calculating Raman Scattering and Raman Optical Activity Spectra

1.4.1
Raman Scattering

If one wishes to simulate the Raman scattering intensities, one is required to calculate the electric dipole–electric dipole polarizability derivatives. Here one can use either the static values, as was done in most early works, or one can take into account the frequency response, as is now routine. In most conventional Raman scattering experiments one uses either 488, 532, or 1064 nm source, the later for molecules for which fluorescence is a problem.

The Raman intensity is proportional to the Raman scattering activity, which is given for the *jth* normal mode Q_j by

$$I_j^{\text{Ram}} = g_j(45\bar{\alpha}_j^2 + 7\bar{\beta}_j^2) \qquad (12)$$

where g_j is the degeneracy of the jth transition, and the electric dipole–electric dipole polarizability tensor derivative invariants $\bar{\alpha}_j^2$ and $\bar{\beta}_j^2$ are given by

$$\bar{\alpha}_j^2 = \frac{1}{9}\left(S_{\lambda\alpha,j}\alpha_{xx}^{\lambda\alpha} + S_{\lambda\alpha,j}\alpha_{yy}^{\lambda\alpha} + S_{\lambda\alpha,j}\alpha_{zz}^{\lambda\alpha}\right)^2 \qquad (13)$$

and

$$\begin{aligned}\bar{\beta}_j^2 = \frac{1}{9}\Big\{&(S_{\lambda\alpha,j}\alpha_{xx}^{\lambda\alpha} - S_{\lambda\alpha,j}\alpha_{yy}^{\lambda\alpha})^2 \\ &+ (S_{\lambda\alpha,j}\alpha_{xx}^{\lambda\alpha} - S_{\lambda\alpha,j}\alpha_{zz}^{\lambda\alpha})^2 \\ &+ (S_{\lambda\alpha,j}\alpha_{yy}^{\lambda\alpha} - S_{\lambda\alpha,j}\alpha_{zz}^{\lambda\alpha})^2 \\ &+ 6[(S_{\lambda\alpha,j}\alpha_{xy}^{\lambda\alpha})^2 + (S_{\lambda\alpha,j}\alpha_{yz}^{\lambda\alpha})^2 \\ &+ (S_{\lambda\alpha,j}\alpha_{xz}^{\lambda\alpha})^2]\Big\}\end{aligned} \qquad (14)$$

respectively. The $S_{\lambda\alpha,j}$ matrix relates the normal coordinates Q_j to the Cartesian displacement coordinates $X_{\lambda\alpha}$, where λ specifies a nucleus and $\alpha = x, y, or\ z$ (Diem, 1993): as previously defined. In addition to normal and Cartesian coordinates there are symmetry coordinates (Cotton, 1990). The advantage of using symmetry coordinates is that the Hessian will block diagonalize, that is, the Hessian will be reduced to independent sum matrices. Before the advent of supercomputers, symmetry coordinates were used for all symmetrical molecules. They are still used as in the IR and Raman modes for molecules with a center of inversion are mutually exclusive. That is, modes which are active in the Raman and inactive in the IR and vice versa. Here one can make use of character tables (Cotton, 1990). In addition, some modes are not seen in either the Raman or IR,and here the use of IINS can help. The selection rules for IR, Raman and IINS are all different, so the three experiments are complementary and all necessary if one wishes to get complete data for all of the vibrational modes.

The normal frequencies are the eigenvalues Λ of the Hessian matrix H (the second derivative of the energy with respect to nuclear displacements, evaluated at the equilibrium geometry):

$$H_{\lambda\alpha,\lambda'\alpha'} = \left(\frac{\partial^2 E(\mathbf{R})}{\partial X_{\lambda\alpha}\partial X_{\lambda'\alpha'}}\right)_{\mathbf{R}=\mathbf{R}_o} \qquad (15)$$

and

$$C^{-1}HC = \Lambda \qquad (16)$$

C is the eigenvector matrix, which defines the transformation matrix S which is given by

$$S = M^{-1/2}C \qquad (17)$$

where M is the mass matrix.

Therefore, through the matrix S (obtained by diagonalizing the Hessian matrix) and the polarizability derivatives (Electric Dipole-Electric Dipole Polarizability Derivatives EDEDPD), $\alpha_{\beta\gamma}^{\lambda\alpha}$, one can obtain the Raman scattering activity $\mathrm{I}_j^{\text{Ram}}$ of any normal mode Q_j. The first efficient method for determining the EDEDPD was implemented utilizing finite field perturbation theory by Komornicki and McIver (1979). Subsequently the analytical EDEDPD were derived and implemented in CADPAC (Amos, 1986,

1987) and Gaussian (Frish *et al.*, 1986) at the Hartree–Fock level of theory, and subsequently at the DFT level. The ED-EDPD have also been implemented at the DFT level and used to simulate the Raman spectra without any solvent treatment (Johnson and Florian, 1995; Stirling, 1996; Collier, Magdo and Klots, 1999; Halls and Schlegel, 1999a; van Caillie and Amos, 2000; Jalkanen *et al.*, 2006b) and subsequently by treating the solvent with explicit solvent molecules, with continuum solvent models, and finally using hybrid models which combine the two (Jürgensen and Jalkanen, 2006; Jalkanen *et al.*, 2006a, 2008a; Deplazes *et al.*, 2008). In contrast to solvent subtraction which is common in IR/VA spectroscopy, this is not always done with Raman measurements. Investigations of the performance of local, gradient-corrected, and hybrid density functional models in predicting Raman intensities have shown that the hybrid functionals are very accurate when the solvent effects are not important (Halls and Schlegel, 1999b; Jalkanen *et al.*, 2006b).

Hence the question of whether and how to perform a solvent subtraction for Raman measurements is a question that we and others have started to address (Jalkanen *et al.*, 2001, 2003, 2008a; Han *et al.*, 1998; Tajkhorshid, Jalkanen and Suhai, 1998).

1.4.2
Raman Optical Activity

Finally if one wishes to simulate the ROA intensities, one is required to calculate the electric dipole–magnetic dipole polarizability derivatives (ED-MDPD) and the electric dipole–electric quadrupole polarizability derivative (ED-EQPD) (Buckingham, 1967; Atkins and Barron, 1969; Barron and Buckingham, 1971, 2001; Fischer and Hache, 2005). The calculation of the EDMDP, G′, have been implemented in CADPAC (Amos, 1982). The EDMDP can be evaluated as the second derivative of the energy with respect to a static electric field and a time varying magnetic field. Hence the ED-MDPD is a third derivative with respect to the nuclear displacement.

$$G'^{\lambda\alpha}_{\beta\gamma} = \left(\frac{\partial^3 W_G(\mathbf{R}, F_\beta, \dot{B}_\gamma)}{\partial X_{\lambda\alpha}\partial F_\beta \partial \dot{B}_\gamma}\right)_{\substack{\mathbf{R}=\mathbf{R}_o, F_\beta=0,\\ \dot{B}_\gamma=0}} = \left(\frac{\partial G'_{\beta\gamma}(\mathbf{R})}{\partial X_{\lambda\alpha}}\right)_{\mathbf{R}=\mathbf{R}_o} \tag{18}$$

The electric dipole–electric dipole, electric dipole–magnetic dipole, and electric dipole–electric quadrupole polarizability tensors can also be calculated at the frequency of the incident light using SCF linear response theory. London atomic orbitals have been employed, hence the results are gauge invariant (Helgaker *et al.*, 1994). In this work, the electric dipole–magnetic dipole orbitals are gauge independent when using a finite basis set due to the use of gauge-invariant atomic orbitals as implemented in Gaussian 03. Previously we used conventional basis sets which were not gauge invariant, similar to the work of Polavarapu and coworkers (Polavarapu, 1990; Barron *et al.*, 1991a,b; Deng *et al.*, 1996) and our previous work on NALANMA (Han *et al.*, 1998), where that level of theory had been shown to give predicted ROA spectra in good agreement with the experimentally observed spectra. We are thus confident that the new level of theory can be used to answer the structural questions posed here, realizing that the agreement in absolute intensities could be improved by using much larger basis sets, as we shall do for the NALANMA4WC, but not the LA20WC.

The EDEQP, A, can be evaluated as the second derivative of the energy with respect to a static electric field and a static electric field gradient. Hence the EDEQPD is a third derivative, the third derivative being with respect to the nuclear displacement.

$$A^{\lambda\alpha}_{\beta,\gamma\delta} = \left(\frac{\partial^3 W_G(\mathbf{R}, F_\beta, F'_{\gamma\delta})}{\partial X_{\lambda\alpha}\partial F_\beta \partial F'_{\gamma\delta}}\right)_{\substack{\mathbf{R}=\mathbf{R}_0, F_\beta=0,\\ F'_{\gamma\delta}=0}} = \left(\frac{\partial A_{\beta,\gamma\delta}(\mathbf{R})}{\partial X_{\lambda\alpha}}\right)_{\mathbf{R}=\mathbf{R}_0} \qquad (19)$$

The Cartesian polarizability derivatives are required to calculate the ROA spectra. The quantities required have been derived by Barron and Buckingham (1971) and are $\bar{\alpha}_j\bar{G}'_j$, γ_j^2, and δ_j^2 (Barron, 1982, 2004; Buckingham, 1967; Barron, Bogaard and Buckingham, 1973; Hecht and Barron, 1990). The quantities are calculated by combining the various polarizability derivatives with the normal mode vectors in the following equations.

$\bar{\alpha}_j\bar{G}'_j$ is given by

$$\bar{\alpha}_j\bar{G}'_j = \frac{1}{9}\left(S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{xx} + S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{yy} + S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{zz}\right) \times \left(S_{\lambda\alpha,j}G'^{\lambda\alpha}_{xx} + S_{\lambda\alpha,j}G'^{\lambda\alpha}_{yy} + S_{\lambda\alpha,j}G'^{\lambda\alpha}_{zz}\right) \qquad (20)$$

γ_j^2 is given by

$$\begin{aligned}\gamma_j^2 = \frac{1}{2}\Big\{&(S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{xx} - S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{yy})(S_{\lambda\alpha,j}G'^{\lambda\alpha}_{xx} - S_{\lambda\alpha,j}G'^{\lambda\alpha}_{yy}) + (S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{xx} - S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{zz})\\ &\times(S_{\lambda\alpha,j}G'^{\lambda\alpha}_{xx} - S_{\lambda\alpha,j}G'^{\lambda\alpha}_{zz}) + (S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{yy} - S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{zz})(S_{\lambda\alpha,j}G'^{\lambda\alpha}_{yy} - S_{\lambda\alpha,j}G'^{\lambda\alpha}_{zz})\\ &+ 3\Big[(S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{xy})(S_{\lambda\alpha,j}G'^{\lambda\alpha}_{xy} + S_{\lambda\alpha,j}G'^{\lambda\alpha}_{yx}) + (S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{yz})(S_{\lambda\alpha,j}G'^{\lambda\alpha}_{yz} + S_{\lambda\alpha,j}G'^{\lambda\alpha}_{zy})\\ &+(S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{xz})(S_{\lambda\alpha,j}G'^{\lambda\alpha}_{xz} + S_{\lambda\alpha,j}G'^{\lambda\alpha}_{zx})\Big]\Big\}\end{aligned} \qquad (21)$$

and δ_j^2 is given by

$$\begin{aligned}\delta_j^2 = \frac{\omega}{2}\Big\{&(S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{yy} - S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{xx})S_{\lambda\alpha,j}A^{\lambda\alpha}_{z,xy}\\ &+ (S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{xx} - S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{zz})S_{\lambda\alpha,j}A^{\lambda\alpha}_{y,zx}\\ &+ (S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{zz} - S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{yy})S_{\lambda\alpha,j}A^{\lambda\alpha}_{x,yz}\\ &+ S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{xy}(S_{\lambda\alpha,j}A^{\lambda\alpha}_{y,yz} - S_{\lambda\alpha,j}A^{\lambda\alpha}_{z,yy}\\ &+ S_{\lambda\alpha,j}A^{\lambda\alpha}_{z,xx} - S_{\lambda\alpha,j}A^{\lambda\alpha}_{x,xz})\\ &+ S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{xz}(S_{\lambda\alpha,j}A^{\lambda\alpha}_{y,zz} - S_{\lambda\alpha,j}A^{\lambda\alpha}_{z,zy}\\ &+ S_{\lambda\alpha,j}A^{\lambda\alpha}_{x,xy} - S_{\lambda\alpha,j}A^{\lambda\alpha}_{y,xx})\\ &+ S_{\lambda\alpha,j}\alpha^{\lambda\alpha}_{yz}(S_{\lambda\alpha,j}A^{\lambda\alpha}_{z,zx} - S_{\lambda\alpha,j}A^{\lambda\alpha}_{x,zz}\\ &+ S_{\lambda\alpha,j}A^{\lambda\alpha}_{x,yy} - S_{\lambda\alpha,j}A^{\lambda\alpha}_{y,yx})\Big\}\end{aligned} \qquad (22)$$

The equations relating these tensor derivatives to the ROA spectra are given by Barron (1982, 2004); Hecht, Barron and Hug (1989), and Barron *et al.* (1994). These references provide a good introduction to the theory and application of ROA spectroscopy. Here we shall give the relevant equations for completeness. We follow very closely the notation of Barron from his Faraday Discussions review article (Barron *et al.*, 1994).

The commonly reported quantity from ROA measurements is the dimensionless circular intensity differential (CID) defined as

$$\Delta_\alpha = \left(\frac{I_\alpha^R - I_\alpha^L}{I_\alpha^R + I_\alpha^L}\right) \tag{23}$$

where I_α^R and I_α^L are the scattered intensities with linear α polarization in right- and left-circularly polarized incident light. In terms of the quantities, EDEDPD, EDMDPD and EDEQPD, the CIDs for forward, backward, and polarized and depolarized right-angle scattering from an isotropic sample for incident laser light are (Barron *et al.*, 1994):

$$\Delta(\text{forward}) = \left(\frac{8[45\alpha G' + \beta(G')^2 - \beta(A)^2]}{2c[45\alpha^2 + 7\beta(\alpha)^2]}\right) \tag{24}$$

$$\Delta(\text{backward})_{\text{ICP}} = \left(\frac{48[\beta(G')^2 + (1/3)\beta(A)^2]}{2c[45\alpha^2 + 7\beta(\alpha)^2]}\right) \tag{25}$$

$$\Delta(90^\circ, \text{polarized}) = \left(\frac{2[45\alpha G' + 7\beta(G')^2 + \beta(A)^2]}{c[45\alpha^2 + 7\beta(\alpha)^2]}\right) \tag{26}$$

$$\Delta(90^\circ, \text{depolarized}) = \left(\frac{12[\beta(G')^2 - (1/3)\beta(A)^2]}{6c\beta(\alpha)^2}\right) \tag{27}$$

$$\Delta(\text{backward})_{\text{DCP}_I} = \left(\frac{48[\beta(G')^2 + (1/3)\beta(A)^2]}{2c[6\beta(\alpha)^2]}\right) \tag{28}$$

where c is the speed of light and the isotropic invariants are defined as

$$\alpha = (1/3)\alpha_{\alpha\alpha} \tag{29}$$

and

$$G' = (1/3)G'_{\alpha\alpha} \tag{30}$$

and the anisotropic invariants as

$$\beta(\alpha)^2 = (1/2)(3\alpha_{\alpha\beta}\alpha_{\alpha\beta} - \alpha_{\alpha\alpha}\alpha_{\beta\beta}) \tag{31}$$

$$\beta(G')^2 = (1/2)(3\alpha_{\alpha\beta}G'_{\alpha\beta} - \alpha_{\alpha\alpha}G'_{\beta\beta}) \tag{32}$$

$$\beta(G')^2 = (1/2)(3\alpha_{\alpha\beta}G'_{\alpha\beta} - \alpha_{\alpha\alpha}G'_{\beta\beta}) \tag{33}$$

$$\beta(A)^2 = (1/2)\omega\alpha_{\alpha\beta}\varepsilon_{\alpha\gamma\delta}A_{\gamma\delta\beta} \tag{34}$$

Using these expressions, we can calculate the ROA spectra within the harmonic approximation for the vibrational frequencies and with the static field limit for the EDEDPD, EDMDPD, and EDEQPD. In addition, one can take into account the frequency dependence of the Raman and ROA intensities. A new formalism for the Raman and ROA intensities in the near resonance regime has recently been presented by Nafie, though not yet implemented (Nafie, 2008). Finally the analytical derivatives of the G' and A tensors have recently been reported by Cheeseman and Frisch (2008); Ruud (2008); Liegeois and Champagne (2008); Liegeois (2008). Hence the efficiency of calculation of Raman and ROA spectra is now the same as that for VA and VCD spectra. The availability of commercial Raman and ROA and VCD and VA spectrometers and programs to simulate the spectra has been a major breakthrough in the use of these spectroscopies in quantum nanobiology, molecular biology, and molecular biophysics. In the last section, we now present some interesting and pioneering work on the use of VA, VCD, Raman, and ROA spectroscopy in quantum nanobiology, molecular biology, and molecular biophysics.

1.5
Classifying Conformational States and Structures based on VA, VCD, Raman, and ROA Spectra

1.5.1
Experimental Vibrational Frequencies for *N*-Methylacetamide, NALANMA, Peptides, and Proteins

The amide modes have been determined experimentally from the simple amides formamide, acetamide, and NMA. NMA has been used as a model since its two methyl groups can be assumed to represent the two C_α carbons in proteins. The amide A mode is mainly a N−H stretch, amide I is mainly a C=O stretch, amide II a N−H bend coupled with C−N stretching, amide III N-bending and C−N stretching (only in simple amides as it has been shown to couple with the CH deformations on the adjacent C_α carbons with C−HR groups [nonglycine] (Diem, 1993; Jalkanen *et al.*, 2003), amide IV OCN bending, amide V in-plane N−H bending, amide VI out-of-plane N−H bending, and finally amide VII skeletal torsion (Jung, 2000; Jalkanen and Suhai, 1996). In addition to the amide modes for NMA being identified from both experimental and theoretical studies, these have also been identified in a number of peptides and proteins and the amide frequencies have been correlated with secondary structural elements (Jung, 2000). The mode most often correlated with secondary structure is the amide I mode (called *amide I'* when measured in D_2O). The amide I frequencies need to be measured in D_2O because the amide I mode overlaps with the H_2O bending modes. Hence running the spectra in D_2O when one wants to determine the C=O stretching frequency. Alternatively, one can make up a very concentrated solution and measure the spectra for very thin pathlengths.

In addition, by performing ^{13}C isotopic substitution for the C′ carbon in specific residues, one can shift the frequency of the amide I band for the specific residue. To date, the IR spectra of proteins and their corresponding amide I spectrum have been used to only determine the percent of a specific secondary structural element present, and one has not been able to determine the specific backbone angles for the specific residue and the corresponding side chain angles. This information for each residue would uniquely identify the structure of the protein and is the goal of the combined use of VA, VCD, Raman, and ROA spectroscopy, as has been achieved for both X-ray and neutron diffraction and NMR spectroscopies. In the next section, we review our and other groups theoretical vibrational spectra simulations for amino acids and peptides and present our new work on LALA and NALHNMA. The complete work on the later two molecules will be published in a special issue of Theoretical Chemical Accounts which focuses on molecular biophysics and bioinformatics, the Suhai Festschrift, which will appear in 2009. Hence for more details on the work on LALA and NALHNMA refer to the manuscripts in this special issue (Jalkanen *et al.*, 2009a,b).

1.5.2
Results for the DFT Calculations

1.5.2.1 L-Alanine

In Table 1.1, we present results for the LA zwitterionic species, which is the dominant species found in aqueous solution at neutral pH (Jalkanen, Bohr

[a] Zwitterion stabilized by four water molecules.
[b] Zwitterion stabilized by nine water molecules.
[c] Zwitterion stabilized by nine water molecules + solvent model.
[d] Zwitterion stabilized by 20 water molecules + CPCM model, B3PW91.

and Suhai, 1997; Tajkhorshid, Jalkanen and Suhai, 1998; Frimand *et al.*, 2000; Jalkanen *et al.*, 2001). At the RHF level of theory the zwitterion was found to be stable (Barron *et al.*, 1991a), but one of the N−H bond lengths was found to be much longer than the other two. This resulted in the vibrational stretch frequency associated with N−H to be significantly lower in energy than that for the other two N–H bonds. If the three NH bonds were all the same, the three modes would be thought to be approximately the same and vibrational frequencies would be determined by both the local symmetry (thought to be C_{3v}) and the perturbation due to the local environment. Herein lies the additional information which can in theory be extracted from the experimental VA, VCD, Raman, and ROA spectra. Subsequently Yu and coworkers tried to improve the model for the LA zwitterion by embedding the zwitterion with a continuum solvent treatment, using the Onsager continuum model (Onsager, 1936), optimizing the structure and subsequently simulating the Raman and ROA spectra (Yu *et al.*, 1995). At the B3LYP DFT level of theory, we found that the zwitterionic structure was not stable in the isolated state (Jalkanen, Bohr and Suhai, 1997; Tajkhorshid, Jalkanen and Suhai, 1998).

We present three 6-31G* B3LYP zwitterionic structures for LA, two in the presence of four water molecules (Tajkhorshid, Jalkanen and Suhai, 1998) and one in the presence of nine water molecules (Frimand *et al.*, 2000). We also present the 6-31G** and 6-311++G(2d,2p) optimized geometries for one of the zwitterionic structures. As one can see from the basis set effect, as one adds more polarization functions and diffuse functions, the bond length changes are usually less than 0.004 Å. The valence angle changes are usually less than 0.5°. Finally we also present the LA zwitterion completely solvated by 20 water molecules and embedded with the PCM continuum solvent model (Jalkanen *et al.*, 2008).

Initially we solvated the zwitterion by adding water molecules to hydrogen bond with each of the polar groups, and subsequently extracted the positions from classical MD simulations (Tajkhorshid, Jalkanen and Suhai, 1998; Frimand *et al.*, 2000; Jalkanen *et al.*, 2001). In addition to the normal isotopomers of LA, we have additionally looked at the various deuteriated derivatives theoretically and compared to the experimental work of Diem *et al.* (1982); Abdali *et al.* (2002). We have recently determined the positions of the hydrogens and completely solvated the LA zwitterion with BO MD simulations (Degtyarenko *et al.*, 2007) and subsequently have simulated the VA, VCD, Raman, and ROA spectra for the completely solvated zwitterion and embedded within the COSMO and PCM continuum models (Jalkanen *et al.*, 2008a). Finally we have compared the zwitterionic structure derived from molecular dynamic simulations with that found in the crystal (Degtyarenko *et al.*, 2008). Hence the zwitterionic structure of LA has been thoroughly studied. The experimental VA, VCD, Raman, and ROA spectra have been able to be reproduced by treating the first solvation shell of water molecules explicitly and embedding the solvated zwitterionic structure within the continuum solvent models so as to treat the effects due to bulk water molecules. In Figure 1.1, we present the zwitterionic structure of the LAZ hydrated by 20 water molecules and this hydrated complex embedded within the continuum solvent model. As one can see in Figure 1.1 the 4 water molecules in the original LAZ plus 4 water molecules for the F' structure are very similar to 4 of the water molecules in the LAZ plus 20 water molecules. This can explain why the LAZ plus four water molecule plus Onsager model did quite well in reproducing the VA, VCD, Raman, and ROA spectra of the LAZ

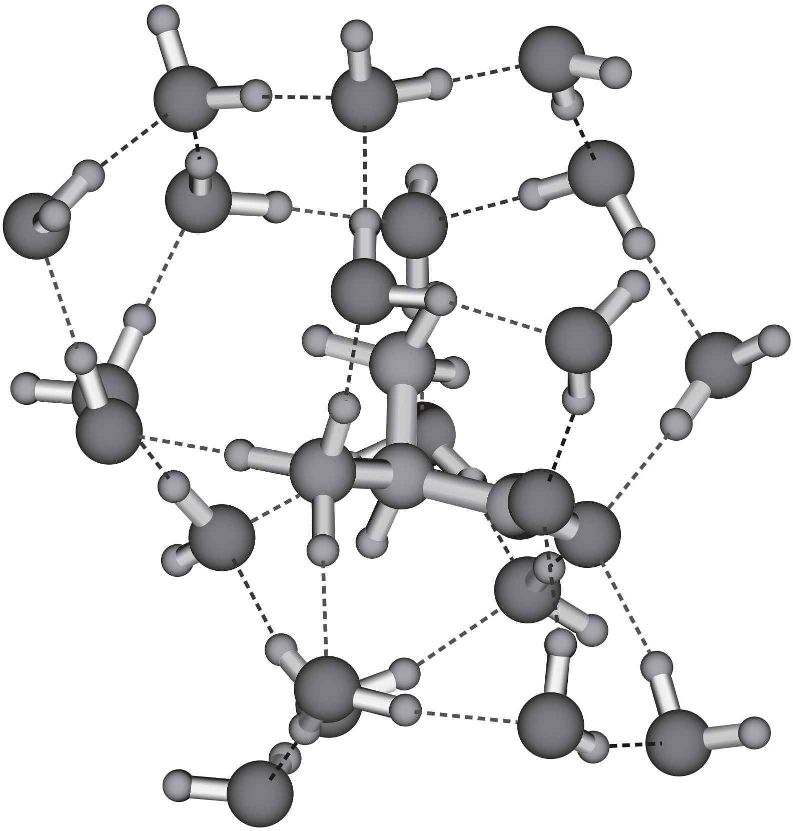

Fig. 1.1 L-Alanine zwitterion stabilized by 20 water molecules. B3PW91/6-31G* plus CPCM continuum solvent model optimized geometry. (Please find a color version of this figure on the color plates.)

(Tajkhorshid, Jalkanen and Suhai, 1998; Jalkanen *et al.*, 2001). Previously we have presented the experimental VA, VCD, Raman, and ROA spectra and the corresponding simulated VA, VCD, Raman, and ROA spectra (Tajkhorshid, Jalkanen and Suhai, 1998; Frimand *et al.*, 2000; Jalkanen *et al.*, 2001, 2008a). We showed that the LAZ plus 20 water molecule model gives better agreement with the experimental spectra, but that our minimal model is a good starting point. Our minimal model being the LAZ plus four water molecule complex embedded in one of the continuum solvent models (Onsager, PCM, CPCM, or Cosmo) (Tomasi, Mennucci and Cammi, 2005).

When one measures the VA, VCD, Raman, and/or ROA spectra, one has the problem of determining the spectra and spectra of the solvent. In many cases one assumes that one can subtract the spectra of the bulk solvent to get the spectra due to the isolated solute. This only applies when the solvent is inert and does not strongly interact with the solute. This is clearly not the case for amino acids and water. As stated above, the water molecules are necessary to stabilize the zwitterionic species. The relative energy of the neutral nonionic species is lower than that of the zwitterionic species, which is not even a stable minima. So one must rethink about how one could in principle subtract out the spectra of the so-called solvent, when the solute and solvent strongly interact. Of course, not all of the solvent molecules strongly interact via hydrogen bonding with the LA zwitterion. Only the first solvation shell waters are thought to be important. In our preliminary works, we included only four and then nine water molecules, but in our last work we included a complete solvation shell, which included 20 water molecules. In addition to the structure of the LA molecule being perturbed by the aqueous environment, the individual water molecules which are hydrogen bonded with the LA zwitterion are perturbed from both isolated water molecules and water molecules in bulk water. In the case of methyl lactate, water molecule(s) bound to polar groups have been shown to possess a VCD signature (Losada and Xu, 2007). Hence on the timescale of the VCD measurement, the water molecules strongly bound to the polar chiral molecule show chirality. Hence chirality can be due to weak hydrogen bonding, in addition to strong covalent bonding. With an increase in temperature the VCD spectra will go away, whereas a drop in temperature will make other water molecules less mobile and hence increase the VCD and also the ROA spectra. Hence by cooling down the aqueous solution of biomolecules, one should be able to learn more about the character of the hydration shells of biomolecules. From these temperature-dependent spectra one should be able to identify various water molecules in the first solvation shell, the strength of their binding, and their exchange rates and mobilities. This should also be the case for ligands bound in the binding pockets (active sites) of proteins.

In Tables 1.2a and 1.2b we present the calculated frequencies and VA and VCD intensities for the zwitterionic structures of L-alanine-d_0 We also give the experimental results reported by Diem and coworkers. In Table 1.2a we also give the calculated vibrational frequencies and VA intensities recently reported by Barron and coworkers. For a complete review of our works on LA, see our latest publication in the Stephens Festschrift in 2008 (Jalkanen *et al.*, 2008a).

1.5.2.2 ***N*-Acetyl L-Alanine *N′*-Methylamide**

In addition to the individual amino acids, one is interested in the amino acid residue as they appear in peptides and proteins. To model the amino acid in a protein, we have capped the LA amino acid with an *N*-acetyl group on the N-terminus and a *N′*-methylamide on the C-terminus. Some researchers have capped the N-terminus with the *N*-formyl group and the C-terminus with the simple amide group. In our work the methyl groups approximate the C_α carbon atoms in the adjacent residues, whereas in the simpler model, hydrogen atoms approximate the C_α carbons. With the speed of computers there is no longer a need to use the simpler model and hence we model our amino acid residues, LA/LH, with the NALANMA and NALHNMA molecules.

In Table 1.3, we present the relative energies of isolated NALANMA and with four bound water molecules. The values of ϕ and ψ (measures of secondary structure in proteins) are also given. The starting structures for the bound water optimizations were the 6-31G* B3LYP

optimized geometries. To each of these structures, four waters molecules were added by the Insight program (Biosym Technologies, San Diego, CA USA). The details of these calculations and the VA, VCD, Raman, and ROA spectra for this molecule have been presented (Jalkanen and Suhai, 1996; Han *et al.*, 1998; Jalkanen *et al.*, 2008a). Here we review the most important results. Note that recent developments by Cao *et al.* have reduced the linear birefringence in VCD measurements, which has increased significantly the sensitivity of modern

VCD instrumentation (Cao, Dukor and Nafie, 2008). This increased sensitivity is very important for amino acid, peptide, and protein VCD measurements in aqueous solution.

In Figure 1.2, we present the structure of the NALANMA plus four water molecular complex (Jalkanen *et al.*, 2008a). As one can see the structures and energetics of this molecule are greatly affected by the solvent, consistent with large changes in the VCD spectra of this molecule when one changes solvent from carbon tetrachloride to water. Note that the C_7^{eq} and C_5^{ext} conformers both converge to the same structure,

[a] Isolated NALANMA, 6-31G* B3LYP relative energies.
[b] NALANMA with 4 bound waters, 6-31G* B3LYP relative energies.

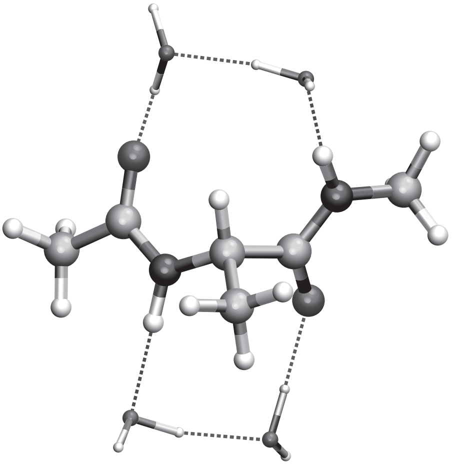

Fig. 1.2 *N*-Acetyl L-alanine *N*′-methylamide stabilized by four water molecules. B3PW91/6-31G* plus CPCM continuum solvent model optimized geometry. (Please find a color version of this figure on the color plates.)

which is the lowest energy structure of NALANMA with four bound waters found till date. This structure has also been used to reanalyze the NMR data for this molecule (Poon *et al.*, 2000; Weise and Weisshaar, 2003). The conclusions from both the NMR and VA, VCD, Raman, and ROA works is that NALANMA plus four water molecule complex is the entity (conformer) of interest, and not the isolated NALANMA molecule (Jalkanen *et al.*, 2008a). The structure of this molecule in aqueous solution had been studied by a variety of both experimental and theoretical methods, but had alluded all previous researchers. The problem had been that most of the previous researchers had failed to take into account the effects of the first solvation water molecules, which are responsible for stabilizing a structure which is not stable on the gas phase isolated-state potential energy surface. This work has been called the gold standard for vibrational spectroscopic structure determination for small peptides. The work on this molecule also documented the importance of measuring not only the VA and VCD or Raman and ROA but also all four spectra in addition to NMR. By measuring all these spectra and getting a structure or set of structures which are consistent with all of the measured spectra, one is able to get a self-consistent picture. This has also been advocated by Serdyuk, Zaccai and Zaccai (2007).

1.5.2.3 L-Alanyl L-Alanine

NALANMA is called the *alanine dipeptide* due to the formation of two peptide bonds by the capping. For biochemists dipeptides have only one peptide bond and keep the N-terminus and C-terminus groups. Hence to model dipeptides, one must now once again treat the N-terminus and C-terminus groups. In aqueous solution at pH 7 once again one has the neutral ionic species, the zwitterionic form of L-alanyl L-alanine.

In Tables 1.4a and 1.4b, we present the structures of zwitterionic structures stabilized by 4, 6, 7, 11, and 17 waters determined, respectively. Here one can see the effect of adding progressively more water molecules. As one can see the more water molecules one adds, the closer the LALA molecule comes to what it would be in aqueous solution. The more water molecules one adds, the more one is able to complete the first solvation shell. The polar groups are enough to hold a small number of water molecule in place, but when one starts to solvate the nonpolar groups one is faced with a problem that during the geometry optimization the water molecules tend to clump together, and this is even without any kinetic energy (i.e. zero temperature). Hence one is faced with the problem of completing the first solvation shell completely, as we have done for LA where we found we needed 20 water molecules to fully encapsulate the LA zwitterion. In a future, study we will completely solvate the LALA zwitterion, but in this work we have only presented and refer to our structures stabilized by 4, 6, 7, 11 and 17 water molecules. In Figure 1.3, we present the LALA zwitterion stabilized by 11 water molecules and the PCM continuum solvent model with the B3PW91 hybrid XC functional and the 6-311G(2d,p) basis set. The 11 water molecules are directly hydrogen bonded to the polar groups, whereas the PCM continuum model is added to treat the effects due to the bulk water. This is similar to our previous works and also the methods recently advocated by Thar, Zhan and Kirchner (2008). In Figure 1.4, we present the simulate VA and VCD spectra for the LALA zwitterion stabilized by 11 waters at the B3PW91/6-311G(2d,p) level of theory including the PCM continuum model, and in Figure 1.5 the corresponding Raman and ROA spectra. In Figure 1.6, we present the LALA zwitterion stabilized by 17 waters and PCM continuum model with the B3PW91 hybrid XC functional and the 6-31G* basis set. In a future work, we will present all of our work on the LALA zwitterion (Jalkanen *et al.*, 2009b).

We also present two zwitterionic structures stabilized by the Onsager model implemented in Gaussian (94, 98, and 03) with and without explicit waters. In addition to the Onsager continuum model, we have optimized the structures of a collection of LALA plus N water molecule complexes, similar to our work for NALANMA with both the PCM and

CPCM continuum solvent models as implemented in Gaussian. The structures were extracted from classical MD simulations of the LALA zwitterion in a box of water molecules (Knapp-Mohammady *et al.*, 1999; Jalkanen *et al.*, 2003, 2009b). Only the waters which were directly hydrogen bonded with the polar groups were kept initially for the full DFT level calculations. This was the protocol which

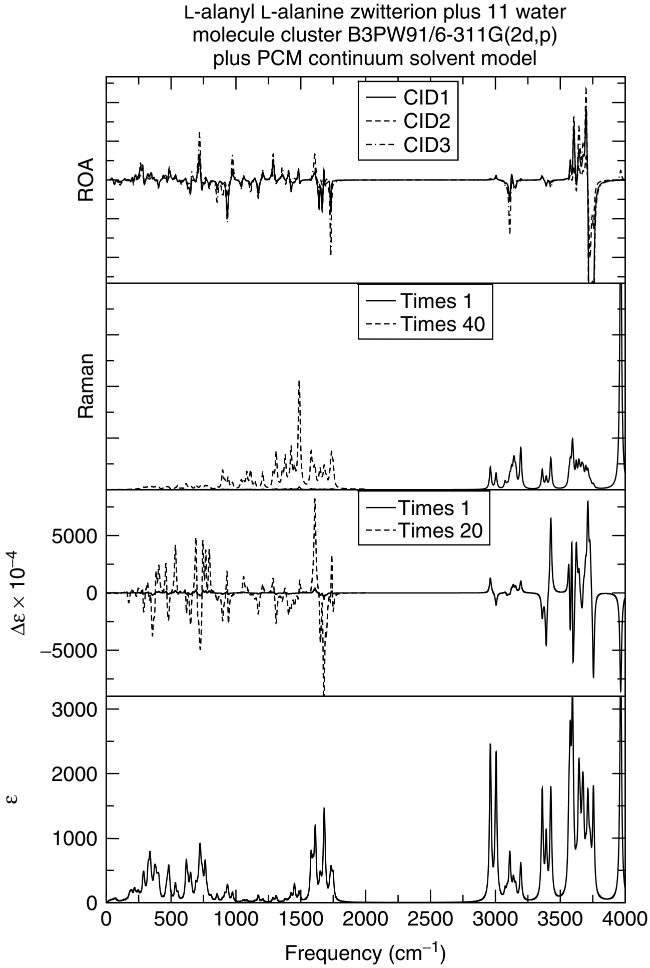

Fig. 1.5 L-Alanyl-L-alanine zwitterion stabilized by 11 water molecules. B3PW91/6-311G2dp plus PCM continuum solvent model for VA, VCD, Raman, and ROA spectra.

worked for LA and NALANMA, but it failed for the LALA zwitterion initially, as mentioned above. Since there is a competition for the hydrogen-bonded partners, some of the water molecules which were initially hydrogen bonded with the polar groups of the LALA zwitterion were pulled away, and hence polar groups of the LALA zwitterion ended up with no hydrogen bonding partners. Our simple solution to this problem was to explicitly add another water molecule to the polar group which now lacked a hydrogen-bonded water partner. The more general problem, which we have used for LA, is to optimize the structure of the solute plus a complete solvation shell. This is of course a much more stable entity than just the solute with the water molecules directly hydrogen bonded to the polar groups of

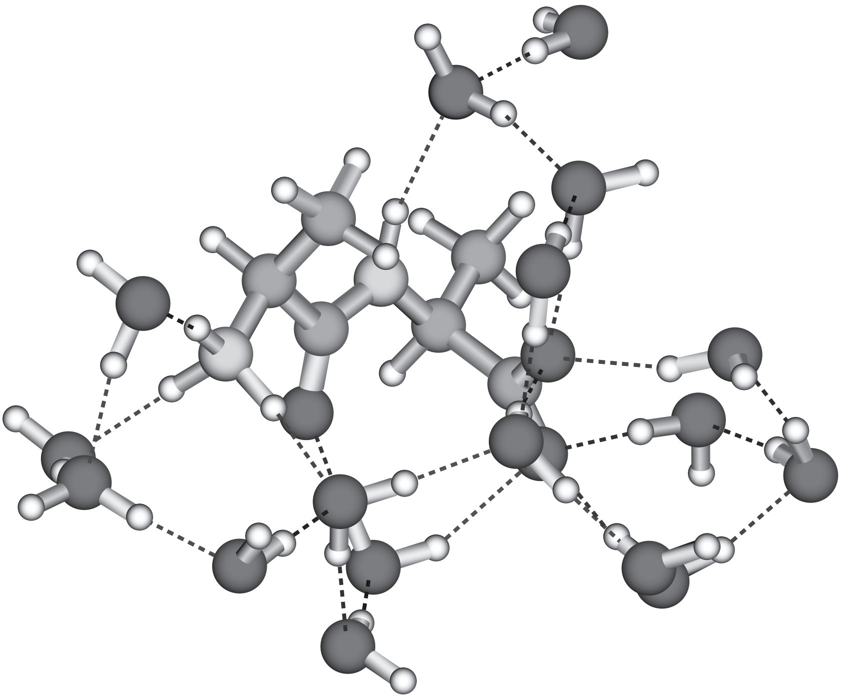

Fig. 1.6 L-Alanyl-L-alanine zwitterion stabilized by 17 water molecules. B3PW91/6-31G* plus PCM continuum solvent model optimized geometry. (Please find a color version of this figure on the color plates.)

the solute. In many cases the hydrogen bonding partners are necessary to orient and stabilize the water molecules that are hydrogen bonded to the polar groups (Degtyarenko *et al.*, 2007, 2008; Jalkanen *et al.*, 2008a).

Our goal is to try to interpret the measured VA, VCD, Raman, and ROA spectra and to be able to determine the structure or structures present under the condition of the experiment. If one cannot determine the conformer and species for simple peptides, one could not be expected to do so for polypeptides like Leu- and Met-enkephalin or proteins. If one wishes to get more than simple secondary structural elements present, which is the backbone and side chain torsion angles for all residues and the protonation state of all polar residues, including the N- and C-termini, then one must extend the methods of vibrational spectroscopy to many dimensions, as was done for NMR, which finally allowed one to get a complete 3D structure. In many cases, in addition to the amino acid, peptide, and protein, one must also include and determine the position of certain water molecules, cations, anions, ligands, and prosthetic groups which are responsible for stabilizing the structure of the molecular complex.

To determine the structure of the LALA zwitterion in aqueous solution requires a conformational search for the lowest energy zwitterionic structure of LALA. The results here only document the feasibility of explicitly adding water to the

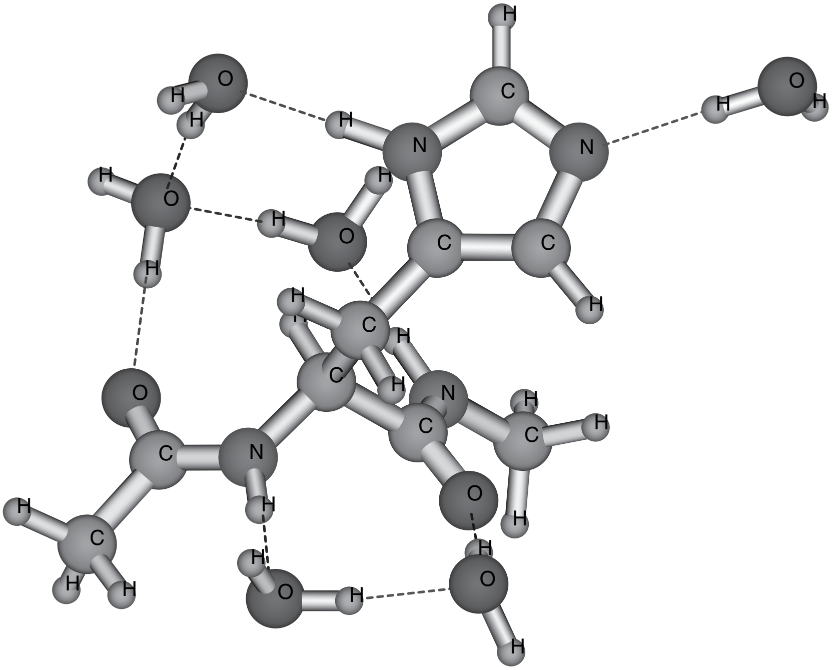

Fig. 1.7 *N*-Acetyl L-histidine *N*′-methylamide stabilized by six water molecules. B3PW91/6-31G* plus PCM continuum solvent model optimized geometry. (Please find a color version of this figure on the color plates.)

calculation of the zwitterionic structures of dipeptides and the calculation of the VA and VCD spectra. Our goal here is be able to determine the structure(s) of the zwitterionic state of LALA in aqueous solution. Our preliminary results show that the VCD spectra is very sensitive to the structure of the zwitterion of LALA and one should be able to distinguish which conformer(s) is(are) present if one knew what the predicted VCD spectra for each conformer was. We are pursuing the determination of the other possible structures of the zwitterion of LALA and will report the complete results in a future publication (Jalkanen *et al.*, 2009b).

In Table 1.5, we present our calculated vibrational frequencies, VA and VCD intensities, for three of the structures presented in Tables 1.4a and 1.4b.

1.5.2.4 **L-Histidine**

In addition to LA, NALANMA, and LALA, one is of course interested in other amino acids. One of the most interesting and functionally important amino acids is LH. Recently we have reported a combined experimental and theoretical study of LH in aqueous solution (Deplazes *et al.*, 2008). For complete details on this work one is referred to that paper. Here we only summarize the results. To determine the structure of LH in aqueous solution one must first stabilize the zwitterionic part of the amino acid. Here we can use the structure of the LA zwitterion, which we determined in our earlier works (Jalkanen, Bohr and Suhai, 1997; Tajkhorshid, Jalkanen and Suhai, 1998; Frimand *et al.*, 2000; Jalkanen *et al.*,

2001) and mutate the methyl group to an imidazole group. Here we have two polar groups, the ring N–H group and the N atom. Following our previous work, we have added two water molecules to hydrogen bond with each group. This is our minimal explicit solvent model. The question we wished to address was what are the two side chain angles, χ_1 and χ_2. Hence we have optimized the structure for the various possible conformers. For the C_α–C_β bond, we have a sp^3–sp^3 bond, and hence one would expect three possibilities, gauche plus, trans, and gauche minus. For the C_β–C_γ bond, we have a sp^3–sp^2 bond, and hence one would expect various possibilities depending on the interactions between the various substituents. Here one could expect cis and trans, in addition to gauche plus and gauche minus. There is the possibility of the N–H group hydrogen bonding with the C=O group of the backbone or with one of the water oxygen atoms. In the presence of explicit water molecules, the backbone C=O oxygen atom would be screened from the ring NH hydrogen atom. Hence one would expect different results for the gas phase isolated state, for implicit solvent models (Onsager, PCM, CPCM, and/or COSMO), for explicit solvent models, and finally for our hybrid model, where we embed the LH + N water molecule complexes within the continuum solvent models. From our comparison with the VA, VCD, Raman, and ROA spectra measurements we concluded that it is important to include explicit water molecules and additionally that the gauche minus gauche minus conformer is the most likely one to be present, though we were not able to definitely rule out the presence of the gauche minus gauche plus.

We have previously presented the structures for the LH zwitterion calculated at the B3LYP/6-31G* plus PCM level of theory and the interested readers can refer to those works (Jalkanen *et al.*, 2006a; Deplazes *et al.*, 2008). In the next subsection, we present our new work on capped LH.

1.5.2.5 *N*-Acetyl L-Histidine *N*′-Methylamide

Similar to capping LA to produce capped LA, one can cap LH to produce capped LH. Here one has the backbone ϕ and ψ angles in addition to the χ_1 and χ_2 side chain angles. In Tables 1.6a,

[a] NALHNMA 6-31G* B3PW91 relative energies.
[b] NALHNMA 6-31G* B3PW91 + PCM relative energies.
[c] NALHNMA 6-31G* B3PW91 + CPCM relative energies.

1.6b, and 1.6c, we present the structures for NALHNMA, NALHNMA plus four water molecule complex, and NALHNMA plus six water molecule complex at the B3PW91/6-31G*, B3PW91/6-31G* plus PCM continuum solvent model and B3PW91/6-31G* plus CPCM continuum solvent model level of theory (Jalkanen *et al.*, 2009a). As one can see in Table 1.6a for the gauche minus gauche minus conformer, structures which are stable within the continuum solvent model are not stable without it. Here the continuum solvent model has effectively taken into account the screening due to to the solvent. In the absence of both explicit solvent molecules or the continuum solvent model, the histidine side chain rotates to form a strong hydrogen bond between the ring N–H group and the *N*-acetyl group C=O group. Hence the importance of taking into account solvent effects. The VA, VCD, Raman, and ROA spectra for all species will be presented in a future work (Jalkanen *et al.*, 2009a). In Figure 1.7, we present one of the conformers of NALHNMA stabilized by the presence of six explicit water molecules (NALHNMA hydrated complex) which has been embedded with the PCM continuum model that treats the effects due to the bulk water molecules.

1.5.2.6 *N*-Acetyl L-Alanine L-Proline L-Tyrosine *N*′-Methylamide

In Figure 1.8, we present one of the 14 structures we have found to date for capped L-alanine L-proline L-tyrosine, *N*-acetyl L-alanine L-proline L-tyrosine *N*′-methylamide at the B3PW91 DFT level of theory. The structures have been extracted from classical molecular dynamics simulations (Nardi *et al.*, 2000; Nardi, 1999; Nardi, Worth and Wade, 1997) and the waters have been removed and the structures have been optimized with the COSMO/PCM hybrid continuum solvation model as implemented in Gaussian 03 (Jalkanen *et al.*, 2009c). Here we have not added explicit water molecules but have only used the continuum solvent treatment to see how well one can do with these larger peptides without actually including the explicit water molecules. In the case of the Raman and ROA spectral simulations, the inclusion of the explicit water molecules increased the cost of the Raman and ROA simulations, but with the new analytical methods developed by Ruud, the tensors required for the Raman and ROA spectral simulations are not longer rate limiting. Here one can calculate the

Hessian, VA, and VCD spectra in one calculation and the tensors required for Raman and ROA in a separate calculation, and then combine the results, that is, the Hessian, normal modes (eigenvalues and eigenvectors) from the first calculation with the EDEDPD, EDMDPD and the EDEQPD from the second, to get the most accurate Raman and ROA intensities. This was advocated earlier for the Raman intensities by Amos (1986), as the basis sets and level of theory to get accurate geometries and Hessians appear to be different than that required for accurate EDEDP, EDMDP, EDEQP and the EDEDPD, EDMDPD and the EDEQPD. But what one must at least be able to get is the structure/conformer which is present in aqueous solution. In our geometry optimizations with the waters removed, the structures stabilized by the waters were not stable (Jalkanen *et al.*, 2009c). This is consistent with our previous work on the alanine dipeptide, showing that this phenomenon for alanine peptide may not be an exceptional case, but the general case. Hence we advocate the use of our hybrid model where one includes the first solvation shell water molecules to treat the effects due to these waters and then embed this hydrated molecule within a continuum

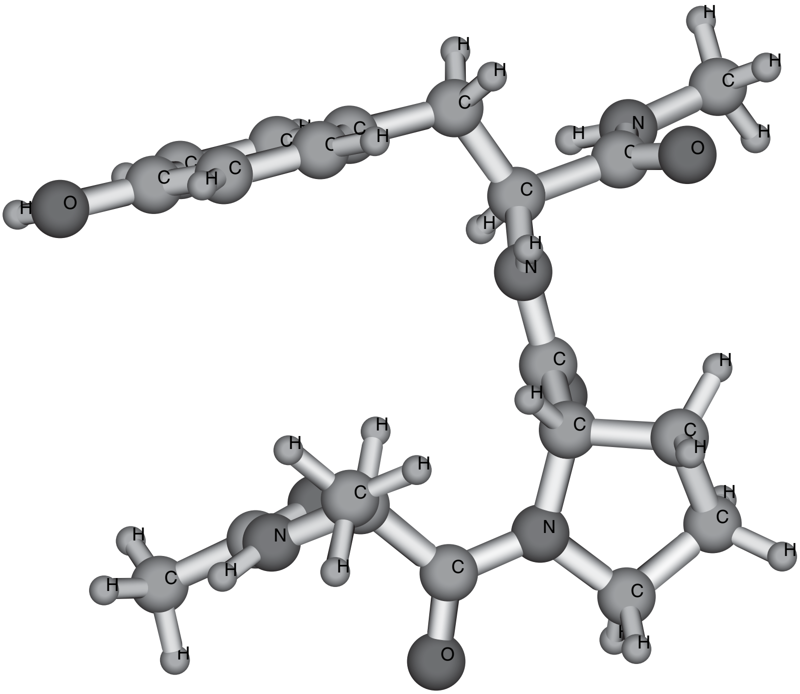

Fig. 1.8 *N*-Acetyl L-alanine L-proline L-tyrosine *N*′-methylamide molecule. B3PW91/6-31G** plus PCM continuum solvent model optimized geometry. (Please find a color version of this figure on the color plates.)

model to treat the effects due to bulk water (Jalkanen *et al.*, 2008a; Deplazes *et al.*, 2008; Frimand *et al.*, 2000; Han *et al.*, 1998; Tajkhorshid, Jalkanen and Suhai, 1998; Jalkanen, Bohr and Suhai, 1997; Jalkanen and Suhai, 1996). In some cases one may even have to include a second layer of water molecule. But the largest and most important effects appear to be due to only the first solvation/hydration layer, so this should be included minimally.

1.5.3
Future Perspectives and Applications for DFT-based Simulations

In this work, we have presented and discussed on the use of DFT simulations and VA, VCD, Raman, and ROA spectroscopy to investigate the conformers of the ligands and proteins and the changes which occur to both on binding. There are of course relevant other approaches to the same problem (Bruno *et al.*, 1997). In addition, the binding of insulin, insulin mimetics, and other ligands to the insulin receptor is an important problem. The insulin receptor is transmembrane receptor with insulin binding to the extracellular part. Recent work has tried to characterize a second ligand binding site of the insulin receptor (Hao, Whittaker and Whittaker, 2006). In addition to the binding of insulin to the extracellular domain, the insulin receptor has an intracellular (cytoplasmic) tyrosine kinase domain, the role of which has also been heavily investigated (Chou, 1990). Here we feel that VA, VCD, Raman, and ROA studies can contribute a lot to a better understanding of the structural changes which occur and to the mechanism/mode of action. Finally, in the last subsection of this work, we extend the multidisciplinary approach to more general problems in molecular medicine and in society in general.

1.5.4

Future Perspectives of the Multidisciplinary Fields of Molecular Biophysics, Molecular Biology, Systems Biology, and Molecular Medicine and Molecular Psychiatry

The future of chemistry, physics and mathematics appears to be secure and healthy through the application and use of the fundamental knowledge gained in these fields in the new fields of molecular biophysics, bionanotechnology and quantum nanobiology (Goodsell, 2002). In addition, the new field of molecular psychiatry has developed to the point where some behavioral disorders have been shown to be correlated with specificity genotypes (Kim-Cohen *et al.*, 2006). Monoamine oxidase A (MAOA) plays a role in regulating behavior by selectively degrading serotonin, norephinephrine, and dopamine following reuptake in the synaptic cleft. If MAOA is underexpressed, children who have been maltreated have been shown to develop conduct disorder, violent behavior and antisocial personalities in adulthood. On the other hand, children who overexpress MAOA do not appear to be affected. These results are very controversial and have not been fully accepted by everyone. Clearly more work needs to be done in this area. The possibility of preventing and/or hindering the antisocial behaviours, conduct disorders, and violent reactions and behaviours by either gene therapy, drugs, and counselling, or a combination of the above would go a long way to solve this problem, which formerly was thought to be only due to poor upbringing and socialization. With the ever increasing prison populations in the United States and China, clearly, any alternatives are well worth exploring. In addition, many of those currently in our prisons and criminal justice system need to be tested for genetic problems that may be partly responsible for behaviours and actions inherent in the genetic makeup.

Hence, in addition to determining tendencies for diabetes, high blood pressure, heart disease, and cancer, there now appear to be genetic markers that are able to predict tendencies for antisocial and combative behavioral patterns when the individuals are psychologically, emotionally, and physically stressed (maltreated, sexually molested, physically abused, and mobbed) as children or young adults. The increasing incidences of violent behavior like the Columbine and Virginia Tech shootings may be able to be prevented by genetically testing young students who have been and continue to be mobbed and socially ostracized. Rather than demonize these young people and their behavior, more research needs to be undertaken to understand the root causes of such behavior and the triggering mechanisms. Many veterans and survivors of the Korean, Vietnam, Gulf 1 and 2, Afghanistan, and Balkan wars have shown similar behavior after being exposed to inhumane treatment and/or seeing atrocities. The increase of extremism appears to be an ever increasing problem and there does not appear to be a lack of researchers trying to shed some light on this international problem (Gambetta, 2005; Abbas, 2005). In addition to psychological, part of the problem may indeed be biochemical. No one is saying that this is the full answer, but this field of research is well worth pursuing. Just like biomolecule interacting in various manners in various environments, it appears that many behavior patterns are the results of a complex set of physical, psychological, societal, economic, religious, and biochemical interactions. Ulcers were thought to be caused by stress, but subsequently were found to be caused by microorganisms, which when the immune response was weakened by other factors, were able to have adverse side effects that did not appear without the physical, mental, and psychological stress.

But these multidisciplinary and multifaceted fields require the researchers and scientists to be on top of many areas of endeavor. The pyramid principle of knowledge never made itself more apparent than in these problems. The idea of social workers, police and military officers, and our criminal justice worker, judges, and politicians are competent to understand these problems is really a fallacy. The systems are broken and this is shown by the record numbers of people being incarcerated in both the United States and China. When having to deal with complex problems, the simple black and white, with us or against us model is clearly not working. The world is not those who are with us and those who are against us. We have learned a lot from complex biological systems to see that the human body is a very complex machine and that when one try to fix one system with a drug, in many cases this causes adverse side effects, which in many cases are even worse than the symptoms one was/is trying to treat. The real root cause of the problem and/or disease is not even known or dealt with. This is the same in many societies, where one tries to treat and/or deal with the symptoms of some social, religious, economic, societal, and/or political problem, and one does not deal with the root cause or causes. We must be smarter and use the scientific method, logic, reasoning, and philosophy, to get to the root causes of the problems we are facing in society, be it behavioral, environmental, economic, and/or with the public and individual health.

Tackling the multifaceted and multidisciplinary problems has changed the paradigm for many departments, funding agencies, government agencies, educational and training institutions, and publishers. The cross-fertilization of knowledge and techniques has never been more fruitful. What has prevented this interaction in the past has been the artificial barriers between what was mathematics, physics, chemistry, biology, medicine, political science, psychology, sociology, anthropology, religious studies, criminal justice, economics, and environmental sciences. We now realize that these barriers were/are really artificial, and, in many cases, these are responsible for some our global problems, like air and water pollution, chemical poisoning of our environment, high increase of allergies, global warming, world hunger, epidemics, terrorism, and the economic crises being experienced by many countries. By introducing new technologies, governmental policies, economic systems, chemicals, and even alternative energy sources, one has bettered mankind and the quality of life in one area, but has had long-term detrimental effects in other areas. The idea that free trade and market economies would be the panacea for increasing the standard of living for everyone on the planet has been a big myth. The trade unions (organized labor), environmentalists, and religious leaders have not been included at the World Trade Organization (WTO) and G8 summit meeting. There has not been a consensus and trust from large segments of society. This has been due to the lack of experts and ideas from many of the major players: organized labor, environmentalists, religious leaders, and native indigenous nations which have been occupied, but who have almost no political, economic, and military strength (Tibetans, Tamil Tigers, Native Americans, Mexican Americans displaced by the land grab by the United States from Mexico: now the states of California, Nevada and Utah, and parts of the states of Wyoming, Texas, Arizona, Colorado, and New Mexico). Many of the 10 million so-called illegal aliens in the United States are a direct result of the failed policies and treaties resulting from the American–Mexican war. A settlement by politicians in Washington DC and Mexico City did not deal with the border problem. This was similar to the problem during the cold war between East and West, but in the Cold War the United States and the West welcomed Eastern Europe with open arms. Many so-called Americans are not so receptive now to accept the children and grandchildren of the Mexican Americans who had their land and resources stolen from them during the American–Mexican war. An open door policy similar to the expanded EU is the only fair, moral, ethical, and social solution of the American-Mexican border. Rather than build another Berlin Wall to keep the Mexican Americans out, the President Barack Obama should tear down the Bush/Republican Berlin Wall. Ronald Regan had it right when he told the Russians to tear down the Berlin wall and now many Mexican Americans and Americans are totally right when they told Bush and the Republicans and now tell Obama and the Democrats to open up the Mexican–American border. It will be a win win for both countries. Of course the elite in both countries who are responsible for the depressed economic conditions in both countries want a status quo. America can be like Finland (bilingual Swedish and Finnish), Switzerland (trilingual German, French, and Italian), and Belgium (bilingual French and Dutch). Note that the people of these three super economies and socially just countries also learn and are fluent in English. It is high time that Mexico and the United States (and also Canada) open their borders and expand like what EU has. If the EU can add 12 new countries and hopefully in the near future Turkey, then the United States, Canada, and Mexico can open their borders and have not only free trade, but free movement of people, thoughts, ideas, religions, resources, and economic wealth and capital. North Americans should all be Americans and not Mexicans, Canadians, Cubans and US-Americans, just like Europeans are no longer Germans, French, Spanish, Portuguese, Finnish, Swedish, and so on. We need to unite and be one, and not continue to separate and deny our brothers and sisters their birthrights and rights as fellow inhabitants of this planet.

The aim of this chapter has been a multidisciplinary and generalist approach to the problems in quantum nanobiology and how they can and have been tackled and approached by various researchers in different fields of endeavor: mathematicians, physicists, chemists, and biologists. Clearly in the future, the next generation of scientists, researchers, and even nontechnology working citizens must be better educated with respect to nature and how we and our machines, devices, vehicles, and energy sources interact with the environment and the world we live in, plant and animal life, as well as our most valuable, but taken for granted resources, pure and clean drinking water. The fate of future generations depends on the next generation being made better aware of the known and possible consequences of newly developed and being developed technologies, so that we can not only maintain our high standard of living in the Western societies but also expand it to the largest two developing nations India and China without them both having the same adverse side effects on their native environments and political systems as we have had. The goal and aim to learn from one's mistakes and errors and from those of others means that we must first admit when we have made errors, fully document them in the open literature, and not take draconian measures against honest mistakes that were made due to lack of knowledge. This will only keep the errors hidden and under the surface and prevent the root causes from being determined. In many cases, the errors and/or failures were due to the systems/approaches which were being used and the inherent assumptions. The more open the discussions and more accessible the data is made, the more honest, caring, and open researchers will tend to be. The faster the problems can be recognized, the quicker the solutions can be made. The withdrawal of the wonder drug Vioxx is a classical example of the new and open system in the field of pharmaceuticals. As soon as problems were recognized the drug was pulled which has allowed top researchers in the whole world to start working on determining and understanding the reasons which caused the adverse side effects, with the hope and goal that the next generation of drug should be even safer than the current generation. Merck is clearly a world leader in not only developing new and better drugs but also in the way to proceed as soon as one recognizes and/or is informed of possible adverse side effects due to one's new drug or technology (small nanoparticles, genetically modified organisms causing allergic reactions for some people).

Not just corporate houses, but each and every scientist, manager, member of the board of directors, and also the Wall Street investment houses need to be more concerned about the long-term sustainability of the world's environment and global standard of living and development instead of focusing only on the short-term bottom line, even if stock options and year end bonuses might suffer and/or be reduced. We owe this to the next generation which will follow us and have to deal with the consequences of our actions, or in many cases, lack of actions, or responses to known and/or possible adverse side effects. We can in many cases no longer claim ignorance. The goal is to rid the world of ignorance and educate not only scientists but also industrialists, politicians, investment bankers, venture capitalists, and of course the citizens and noncitizens globally. A very challenging task, but working with top universities and publishers like John Wiley & Sons, Inc. surely doable, if we put our hearts, souls, and minds to the great task at hand!

Acknowledgments

K.J. Jalkanen (KJJ) would like to thank the Deutscher Akadmemisher Austausch Dienst (DAAD) [German Academic Exchange Service], the Deutsches Krebsforschungzentrum (DKFZ) [German Cancer Research Center] in Heidelberg and the EU for making his five year stay at the German Cancer Research Center and the Steinbeiss Transfer Centrum possible. In addition, he would like to thank the Finnish Academy of Science for sponsoring many visits to Professor Risto Nieminen's Laboratory of Physics Laboratory in Helsinki University of Technology in Espoo, Finland. We would like to thank the Danish Foundation for Fundamental Research (www.dg.dk) for funding the establishment of the Quantum Protein (QuP) Centre in the Department of Physics at the Technical University of Denmark where KJJ has been an associate professor of biophysics before moving to the Nanochemistry Research Institute at Curtin University of Technology where he is currently on unpaid sabbatical leave from QuP and being funded by the Western Australian Premier's Research Fellowship program (grant awarded to Professor J.D. Gale, Western Australian Premier's Research Fellow). KJJ would also like to acknowledge and thank iVEC (The hub of advanced computing in Western Australia) in Perth, APAC (Australian Partnership for Advanced Computing) in Canberra, and the ARC for providing computational, people and financial resources which made parts of this work possible during KJJ's three-year sabbatical stay in Perth at Curtin University of Technology in the Nanochemistry Research Institute (NRI) in the Department of Applied Chemistry. Finally KJJ would like to thank the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) and the DAAD for financial support for his five months stay in the laboratory of Professor Thomas Frauenheim at the Bremen Center for Computational Material Science at the University of Bremen.

2.1
Introduction

Living organisms on the earth are constantly being exposed to UV and other kinds of cosmic and georadiations that, in many instances, are capable of inducing electronic transitions in the atomic and molecular constituents of biomolecules, amino acids, or proteins. In most cases, these biomolecules return to their original states after being excited. The study of the mechanism of restoration of bio-organisms to their original states after being exposed to radiation capable of causing electronic transitions is still in its infancy, and in this chapter we present the current status of the nonradiative process caused by the interaction between two electrons, which is associated with the de-excitation. This process is likely to play a very important role in restoring them to their original states after being exposed to radiation.

It is now well recognized that biomolecules being exposed to electromagnetic radiation (EMR) or to collision by other projectiles such as electrons or protons of sufficient energy can undergo electronic transition from ground states to some excited states. For incident EMR, the wavelength, λ, required for this electronic excitation, is related to its energy, E, by the following relation:

$$E(\text{in eV}) = \frac{(1.237)10^3\ \text{eV nm}}{\lambda(\text{in nm})} \quad (1)$$

The most predominant excitation is caused by the dipole component of EMR and hence, the excited state must have the same electronic spin (but not total angular momentum) as the ground state, which in most of the biomolecules is a singlet state denoted in Figure 2.1 as S_0. Following the resonant absorption, the electron from S_0 is transferred to an excited singlet state, S_{ex}, commensurate with the energy given by Eq. (1), even though there are quite often triplet states at lower or nearby energy. Once the system is in the S_{ex} state, it may not primarily decay back immediately to S_0 because of the opening of many other decay channels. Frequently, intraband vibrational decay probabilities emitting infrared radiation are much faster than the electronic dipole radiation $S_{\text{ex}} \rightarrow S_0$, and hence, the system undergoes some vibronic decays, but then it could move from its original potential well to another one either by internal conversion (IC), caused by electronic–vibrational–rotational coupling, or to another potential well based on the triplet electronic state, T_{ex}, known as

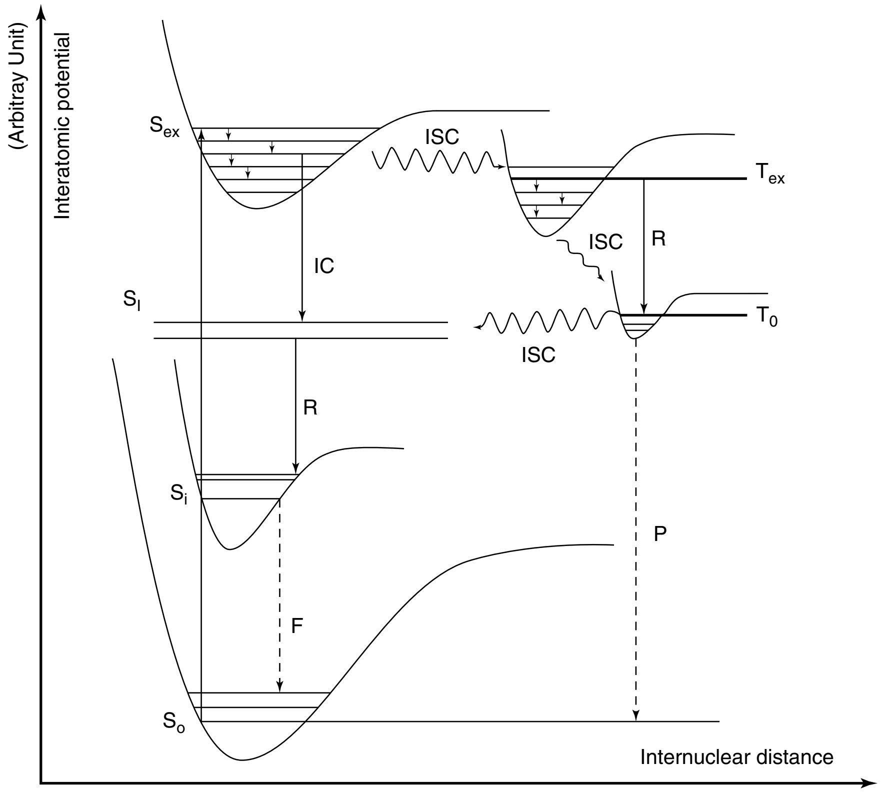

Fig. 2.1 Schematic pathway of radiative excitation and radiative and nonradiative relaxation in a biomolecule. S_0, S_l, S_ℓ, and S_{ex} refer to singlet states, and T_{ex} and T_0 to triplet states. ISC, R, IC, F, and P refer, respectively, to intersystem crossing, radiative transition, internal conversion, fluorescence and phosphorescence. The latter two are also radiative processes. The pathway for the Bio-Auger process is not shown.

intersystem crossing (ISC). The relaxation mechanism to the ground state, S_0, may occur in a variety of ways. For example, following IC, a system could decay to S_i, from which it could, via radiative dipole transition, return to S_0. This delayed radiative transition is termed *fluorescence*. Any one of the triplet states could bring an ISC back to a low-lying singlet state, S_l, which then decays to the ground state by fluorescence again. The relaxation pathway via triplet states to ground state could, however, happen directly by radiative transition of multipole of an order higher than dipole, known in atomic physics as forbidden transitions. In particular, the multipoles must be those capable of causing a triplet–singlet transition. These have long lifetimes and are termed *phosphorescence*. All these relaxation pathways to ground states have been experimentally observed in many polyatomic, aromatic, and nonaromatic organic molecules (McGlynn, Azumi, and Kinoshita, 1969; Lin, 1980; Schwoerer and Wolf, 2005; DiBartolo, 1980; Karplus and Porter, 1970). However, in many cases the total fluorescence and phosphorescence yields, collectively termed as *luminescence yields*, do not account for the magnitude of initial resonant absorption, pointing toward the existence of other decay modes, termed as *nonradiative decay mode*, or radiationless transition.

The study to understand the underlying causes of radiationless transitions started almost half a century ago (Henry and Kasha, 1968). Their occurrence in the relaxation process of biomolecules, particularly for many amino acids, were well established soon thereafter (Maki and Zuclich, 1975). It is now well recognized that many amino acids and proteins, following exposure to laser, (i) populate the triplet states substantially after undergoing ISC, (ii) the luminescence yields are extremely low at room temperature, implying that the transition to the ground state from the triplet state is primarily nonradiative (Pappalardo, 1980), and (iii) the luminescence lifetimes are very long.

In fact, the study of the emission process in radiatively exposed tryptophan, tyrosine, and phenylalanine revealed that, only at very low temperature, the nonradiative decay of the triplet state becomes negligible – in this particular case below 77 K (Maki and Zuclich, 1975). The decay properties of these three amino acids at 77 K are noted (taken from Maki and Zuclich (1975)) in Table 2.1. At higher temperature, the luminescence yields are well below one.

Bohr and his collaborators (Bohr, Jalkanen, and Malik, 2005; Bohr and Malik, 2007) proposed for the first time that the underlying physical process responsible for the radiationless transition in the relaxation of an electronically activated biosystem is akin to the Auger process in the atoms. At about the same time, Srinivasan *et al.* (2005) established "in aromatics such as benzenes and pyridines, upon absorption of light, a substantial portion of the energy is directed in nonradiative pathway" and the nonradiative decay process is a fast one and takes place in a few tenths of a picosecond. In a series of earlier studies, Zewail and his collaborators attributed the radiationless process to electron transfer (Wan *et al.*, 1999, 2000).

In Section 2.2, we present the basic theory of nonrelativistic Auger process in light atoms and atomic ions, which clearly quantifies that the process is a fast one and dominates over the radiative decay in light elements. This is followed by a section where we discuss the features distinguishing Auger

Tab. 2.1 Ultraviolet (UV) absorption and subsequent luminescence data of three aromatic amino acids (Maki and Zuclich, 1975) at 77 K.

processes in atomic systems from similar ones in biomolecules. The refined theory to deal with the Auger-like processes in biosystems, called *Bio-Auger processes*, developed in Bohr, Greissen, and Malik (2008), is presented in Section 2.4. Section 2.5 deals with the relation of the Bio-Auger process and electron or charge transfer. In the last section, we discuss the theoretical interpretation of the Bio-Auger process for biosystems exposed to solar radiation and laser beams for a number of cases including the restoration to the original state of UV activated damaged thymine dimer as it comes into contact with the optically activated photolyase protein and cofactor.

2.2
Auger Process in Atoms

It was discovered in 1926, that a helium-like atomic ion, upon exposure to EMR of enough energy capable of causing an electronic excitation, returns to its ground state primarily by two processes, of which one is radiative transition and the other, the dominant one in light atoms, is the Auger transition named after (Auger, 1923, 1925a, 1925b, 1926), who first demonstrated that an atomic ion with a vacancy in its K shell emits an electron in the process of filling the vacant K shell preponderantly over radiative transition in light elements. Although Klein and Rosseland (1921) in their study of inelastic scattering of electrons by atoms raised the possibility of such a process because of its being a reversible phenomenon to inelastic excitation with electrons, Auger was the first scientist to demonstrate it experimentally, and hence, it is now universally known as the *Auger Process* or the *Auger Effect* in atomic physics and the emitted electron is termed as the *Auger electron*. Auger's experiment was immediately confirmed by de Broglie and Thibaud (1925); Robinson (1926), and Robinson and Cassie (1926). The first comprehensive theoretical understanding of the Auger process was provided by Wentzel (1927), which still forms the basis of all modern theories in atomic physics.

Since then, the Auger process has been studied extensively for many atoms and atomic ions and extensive literature on the subject is available. Some of the monographs and review articles are noted in Burhop (1952); Burhop *et al.* (1972); Chatterji (1976); Åberg and Howat (1982); Craseman (1985); Bambynek *et al.* (1972), and Wuilleemier (1976). The key feature associated with the de-excitation of an atom or atomic ion with a vacancy in one of the inner shells in light elements up to about atomic number, $Z = 30$, is that it is filled primarily by radiationless transition where one of the electrons in occupied upper shells makes a transition to the empty lower shell and another electron from the occupied upper shell takes up the transition energy and is ejected in the continuum. The time to fill a vacancy in a K shell is essentially Z-independent or weakly dependent and of the order of $10^{-14}-10^{-17}$ seconds. The competing fluorescence process involving radiative dipole transition to a vacancy in K shell is strongly Z-dependent and for He-like ions, is slower by a million seconds, that is, the fluorescence lifetime is about 10^{-9} seconds.

For atoms heavier than about atomic number 30, the fluorescence process is faster than the Auger process in filling a K vacancy, but since the biomolecules are primarily composed of lighter elements, it is expected that the Auger-like process would be the dominant one in filling a vacancy.

Wentzel (1927), for helium-like ions, with a nucleus of charge Z, treating the interaction between two electrons as perturbation, showed, using Heisenberg's theory (Heisenberg, 1926), that the emission rate of an electron, $T(\mathrm{el})$, as the other electron makes a transition from L to K shell is

$$T(\mathrm{el}) \cong 10^{15}\ \mathrm{s}^{-1} \tag{2}$$

whereas the rate of emission by an electric dipole $T(E1)$ is about $10^9\ Z^4\ \mathrm{s}^{-1}$. (3)

$$\text{Thus,}\quad T(\mathrm{el})/T(E1) = 10^6\ Z^{-4} \tag{4}$$

Hence, the empty K shell of a helium-like atom is predominately filled by the Auger process up to atomic number of about 36. This important conclusion of Wentzel has essentially proved to be correct both experimentally and theoretically.

In Figure 2.1, taken from Walters and Bhalla (1971), the experimental as well as calculated ratio of K shell fluorescence yield, $\omega_K(R)$, due radiative dipole transition probabilities, $T(R)$, and the total transition probabilities being the sum of $T(A)$, the Auger transition rate, and $T(R)$, is plotted as a function of atomic number. $\omega_K(R)$ in the plot is defined as

$$\omega_K(R) = T(R)/(T(R) + T(A)) \tag{5}$$

The calculated and observed $\omega_K(R)$ are shown, respectively, by dots and a solid line. Clearly for low atomic numbers, the vacancies in K shell are primarily filled by the Auger transition and not radiative transitions. This point is further illustrated in Figure 2.2 taken from Walters and Bhalla (1971), where calculated Auger and dipole X-ray rates are individually plotted as a function of atomic number in filling a vacancy in K shell by electrons from L shell and once again in light atoms, vacant K shell is filled by the Auger transition predominantly.

The calculations illustrated in Figures 2.2 and 2.3 are based on a refined version of Wentzel's theory. The rate of the Auger Process is not independent of atomic number, but is weakly dependent and is about 10^{-17} seconds in light elements. An appropriate theory for Auger-like transitions in biomolecules at much lower energies, noted in a subsequent section, is developed in analogy with the nonrelativistic version of the theory of the Auger transition in atomic systems in Section 2.4.

2.2.1
Nonrelativistic Expression for Auger Processes in Atoms and Ions

We first present the basic theory of nonradiative transition involving relaxation of atoms and ions having a vacancy in one of the inner shells that is valid for light atoms, that is, the basic theory of the Auger process. For light atoms, the relativistic effects can be neglected and hence, we shall present the nonrelativistic approach. The transition probabilities, $T(i \rightarrow f)$ of a system from an initial state $|i\rangle$ to a final state $|f\rangle$ due to a perturbing potential, $H(p)$, can be obtained from a first-order time-dependent perturbation theory in the limit of time, $t \rightarrow \infty$ (Walters and Bhalla, 1971; Asaad and Burhop, 1958) and is given by

$$T(i \rightarrow f) = \frac{2\pi}{\hbar} |\langle f|H(p)|i\rangle|^2 \rho_f \tag{6}$$

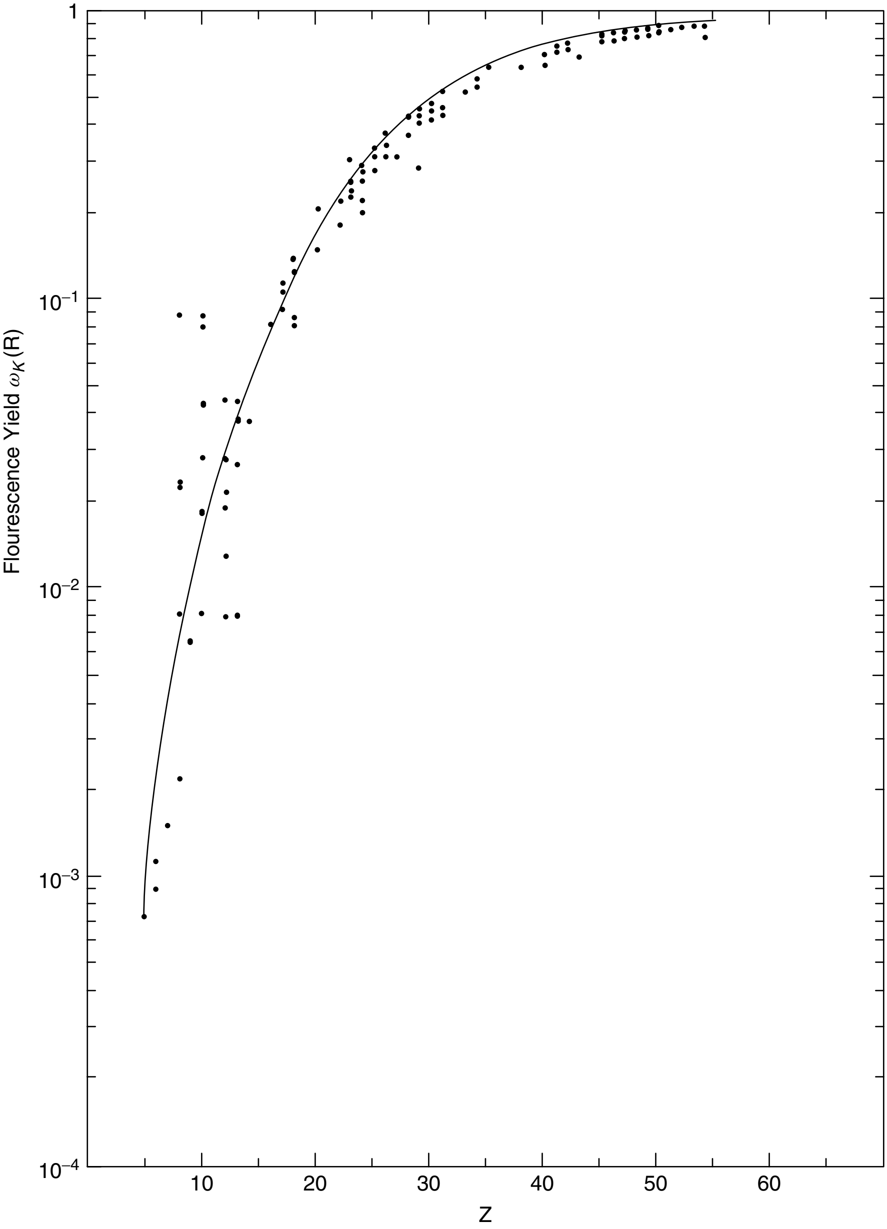

Fig. 2.2 Relative fluorescence yield defined by Eq. (5) is plotted as a function of atomic number *Z* for filling of the K shells in atoms taken from Walters and Bhalla (1971). Solid lines and dots are, respectively, theoretical calculations of Walters and Bhalla (1971) and experimental results noted in Walters and Bhalla (1971).

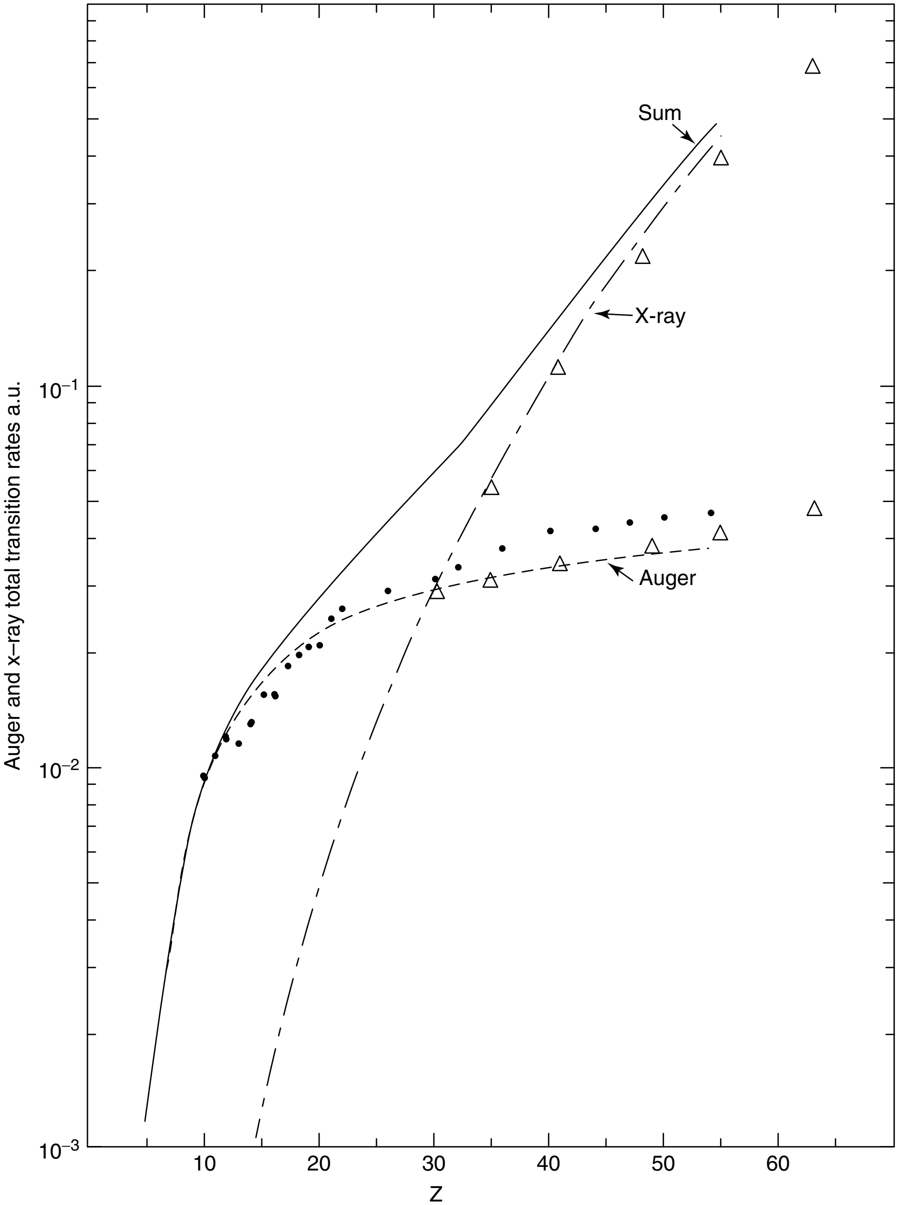

Fig. 2.3 Theoretical calculations of the Auger and X-ray rates done in Walters and Bhalla (1971), noted as Auger and X-ray, respectively, are plotted as a function of the atomic number *Z*. Experimental data for X-ray and Auger processes are shown as open triangles. The sum of theoretically calculated processes is shown as a solid line. au stands for atomic unit and 1 au for transition rate = 2.43 × 10^{-17} seconds. Taken from Walters and Bhalla (1971).

where ρ_f is the density of the final state. This is quite often referred to as the *golden rule of Fermi*. Since the process involves the transition of two electronic states, the initial and final states are, in the simplest approximation, the antisymmetric product of two electronic wave functions. Thus,

$$|i\rangle = [\varphi_\alpha(i)\varphi_\beta(j) - \varphi_\alpha(j)\varphi_\beta(i)] \tag{7}$$

and

$$|f\rangle = [\varphi_\gamma(i)\varphi_\delta(j) - \varphi_\gamma(j)\varphi_\delta(i)] \tag{8}$$

In Eqs (6)–(8), (i) and (j) stand for all coordinates of two electrons involved in the process, and (α, β) and (γ, δ) represent the complete set of quantum numbers of two electrons in the initial and the final states, respectively.

In the usual calculation of the Auger process in atoms and ions, the perturbing interaction, $H(p)$, is taken to be the unscreened Coulomb potential between two electrons involved in the transition, that is,

$$H(p) = e^2/|r_i - r_j| \equiv e^2/r_{ij} \tag{9}$$

where r_{ij} is the distance between two electrons, which can be expanded as follows:

$$\frac{1}{r_{ij}} = 4\pi \sum_{k,m} \frac{(k-|m|)!}{(k+|m|)!}\ \frac{r_<^k}{r_>^{k+1}} \times Y^*_{k,m}(\theta_i\varphi_i)Y_{k,m}(\theta_j\varphi_j) \tag{10}$$

In Eq. (10), the $Y_{k,m}$'s are normalized spherical harmonics and $r_<$ and $r_>$ are, respectively, the smaller and the larger of r_i and r_j.

Expanding φ's in spherical polar coordinates, for example,

$$\varphi_\alpha(i) = [P_{n_\alpha \ell_\alpha}(r_i)/r_i]Y_{\ell_\alpha m_\alpha}(\theta_i\varphi_i) \tag{11}$$

and similarly for φ_β, φ_γ, and φ_δ, one can evaluate the matrix element of Eq. (10) between final and initial states in the L–S coupling leading to (Burhop *et al.*, 1972; Walters and Bhalla, 1971)

$$\begin{aligned}\langle f|i/r_{ij}|i\rangle &= \tau(-1)^{L+\ell_\alpha+\ell_\delta} \\ &\times \sum_k \Bigg[R_k(\alpha,\beta,\gamma,\delta)\langle \ell_\gamma \| C^k \| \ell_\alpha\rangle \\ &\times \langle \ell_\delta \| C^k \| \ell_\beta \rangle \begin{Bmatrix} \ell_\gamma \ell_\delta L \\ \ell_\beta \ell_\alpha k \end{Bmatrix} \\ &+ (-1)^{L+S} R_k(\alpha,\beta,\gamma,\delta)\langle \ell_\gamma \| C^k \| \ell_\beta \rangle \\ &\times \langle \ell_\delta \| C^k \| \ell_\alpha \rangle \begin{Bmatrix} \ell_\gamma \ell_\delta L \\ \ell_\alpha \ell_\beta k \end{Bmatrix} \Bigg]\end{aligned} \tag{12}$$

where

$$\langle \ell_i \| C^k \| \ell_j \rangle = [(2\ell_i+1)(2\ell_j+1)]^{1/2} \times \begin{pmatrix} \ell_j & k & \ell_i \\ 0 & 0 & 0 \end{pmatrix} (-1)^{\ell_i}, \quad \begin{matrix} i = \gamma, \delta \\ j = \alpha, \beta \end{matrix} \tag{13}$$

In Eqs (12) and (13), the brackets represent $(6-j)$ and $(3-j)$ symbols of Wigner, respectively (Brink and Satchler, 1962). In evaluating Eq. (12), the antisymmetric nature of the wave functions in the initial as well as in the final state is taken fully into account and $\tau = 1$ if $(n_\alpha \ell_\alpha) \neq (n_\beta \ell_\beta)$ and $\tau = 1/\sqrt{2}$ if $(n_\alpha \ell_\alpha) = (n_\beta \ell_\beta)$. The symbol $R_k(\alpha, \beta, \gamma, \delta)$ represents the integration over the radial part,

$$\begin{aligned}R_k(\alpha,\beta,\gamma,\delta) &= \int_0^\infty dr_i P_{n_\alpha \ell_\alpha}(r_i) \\ &\times \left[\frac{1}{r_i^{k+1}} \int_0^{r_i} dr_j r_j^k + r_i^k \int_{r_i}^\infty \frac{dr_j}{r_j^{k+1}} \right] \\ &\times P_{n_\beta \ell_\beta}(r_j) P_{n_\gamma \ell_\gamma}(r_j) P_{n_\delta \ell_\delta}(r_i)\end{aligned} \tag{14}$$

The expression (14) is strictly true when $|i\rangle$ is a closed shell, but similar expressions are also valid for unfilled shells. In the atomic Auger process, $(n_\delta \ell_\delta)$ represents an ejected electron in a continuum state.

The calculated Auger transition shown in Figures 2.2 and 2.3 used these expressions with radial solutions of the self-consistent Hartree–Fock equations.

2.2.2
Expression for Radiative Transition

It is of interest to compare this expression with the one for radiative transition probability, $T(\text{rad}, i \rightarrow f)$, which is given by (Blatt and Weisskopf, 1952)

$$T(\text{rad}, i \rightarrow f) = 8\pi \left[\sum_{k=0} \frac{(k+1)}{k[(2k+1)!!]^2} \times (1/\hbar)(E_T/\hbar c)^{2k+1} B(k, I_i \rightarrow I_f) \right] \quad (15)$$

In Eq. (15), k is the polarity of the transition, E_T is the transition energy that is equal to the energy difference between the initial and final states, and $B(k, I_i \rightarrow I_f)$ is the reduced transition probability given by

$$B(k, I_i \rightarrow I_f) = (2I_i + 1)^{-1} \sum_{M_i M_f} \times |\langle f|O(k,m)|i\rangle|^2 \quad (16)$$

In Eq. (16), $O(k, m)$ is the electrostatic multipole operator of order k and z-projection m. I_i and I_f are the total spin of the initial and final states with respective z projection of M_i and M_f. The monopole term in Eq. (16) is zero because of the orthonormality of the initial and final wave functions. Noting that in atoms and molecules E_T is a few electron volts and $\hbar c = (197.327) \times 10^1$ eV Å, the dominant term in Eq. (16) is the dipole term, $k = 1$ in the summation. For dipole transition,

$$T(\text{rad}, i \rightarrow f) = 8\pi(2/3)(1/\hbar) \times (E_T/\hbar c)^3 B(1, I_i \rightarrow I_f) \quad (17)$$

A comparison of the integration over the radial part Eq. (14) involved in an Auger transition with that involved in $B(1, I_i \rightarrow I_f)$ in a radiative transition reveals that the dipole term in the two cases is identical if one omits the first integration in Eq. (14) and extends the lower limit in Eq. (14) to zero because of the normalization of $P(r_j)/r_j$ to one.

For a quick estimate, it is quite useful to use the classical expression for dipole transition, $T(1)$ given by (Heitler, 1954)

$$T(1) = (e^2/\hbar c^3)\nu^3 a^2 = \alpha(\nu a/c)^2 \nu \quad (18)$$

where α, ν, and a, respectively, are the fine structure constant (1/137.06), the transition frequency, and dipole length.

2.2.3
Bethe–Heitler Approximation for Auger Transition

In Eq. (9), one of the wave functions in the final state is outgoing continuum wave function, for example, $(rxP_{n_\delta \ell_\delta}(r_i))$, which is quite often approximated by a plane wave, $e^{ik_i \bullet r_i}$, which can be expanded as

$$e^{ik_i \bullet r_i} = \sum_{\ell=0}^{\infty} (2\ell+1) i^\ell j_\ell(k_i r_i) P_\ell(\cos\theta_i) \quad (19)$$

where j_i is the spherical Bessel function and θ_i, the angle between k_i and r_i.

Sometimes, in the matrix element Eq. (12), the initial state $P_{n_\alpha \ell_\alpha}(r_i)$ is also taken to be the radial part of a plane wave expansion Eq. (19). The situation is then akin to electron-impact ionization, first formulated by Bethe (1930). This approximate form of Eq. (12), known as the *Bethe approximation to the Auger Process*, has been applied to negative meson induced Auger transition in atoms (Lewis and Bethe, 1962).

Furthermore, if the integration over (dr_j) in the term in the square bracket in Eq. (14) is simply taken to be a single integral with limits from zero to infinity, the expression, as noted earlier, reduces to the matrix elements of electrostatic multipole transition, the dominant term being the dipole term. This is also termed sometimes as the *Bethe approximation*. For a quick estimate of the Auger transition rates, sometimes the classical expression of Heitler Eq. (18) for the dipole term is used, as was done in Bohr and Malik (2007). This is known as the *Bethe–Heitler approximation*.

2.2.4
Key Distinctions between Radiative and Auger Transitions

Whereas the operator acting on the particles involved in EMR is a one-body operator, that operating on particles responsible for the Auger transition is a two-body operator.

In case, particles undergoing radiative transition move in a well-defined mean field with very little correlation, radiative transitions involve transitions between two quantum states of a single particle. In the presence of correlations, radiative transitions can cause a change of quantum states of multiparticles, for example in the photo-ionization of the He-like ions; in a few percentage of cases, two electrons are emitted, but this is a relatively rare occurrence. But in all cases involving EMR, photons are emitted or absorbed.

The Auger process, on the other hand, is initiated by direct interaction between at least two particles. In case of electrons, quite often, the Auger transition is caused by electrostatic interaction between at least two electrons in a nonrelativistic case and the Møller interaction between two electrons in the relativistic situation. However, it may not be bare electromagnetic interaction but could be a modified version of it, because of the shielding of the interaction due to the presence of other electrons. Hence, the Auger transition is a nonradiative process. The Auger transition in atoms or ions is characterized by the transition of one electron from an excited state to an empty lower state, whereas another electron is emitted to a continuum or higher excited state by taking up the transition energy.

In case radiative transition is a dipole one, only transitions among the singlet state, for example $S_{\mathrm{ex}} \rightarrow S_0$ in Figure 2.1, or among the triplet states, for example $T_{\mathrm{ex}} \rightarrow T_1$ in Figure 2.1, are possible. On the other hand, Auger transitions could occur between triplet and singlet, singlet and singlet, and triplet and triplet states.

2.3
Distinctive Features of the Auger Processes in Atoms and those in Biomolecules

Bohr and his collaborators Bohr, Jalkanen, and Malik (2005); Bohr and Malik (2007) proposed for the first time that radiationless transitions akin to the Auger process in atoms could occur in

UV-activated biosystems. In particular, this process is responsible for repairing UV-induced damaged thymine dimer coming in contact with optically exposed photolyase, as observed in the experiment conducted by Mees *et al.* (2004). At about the same time, the experiment of Srinivasan *et al.* (2005) seems to establish that biomolecules in particular, being exposed to laser-induced electronic transition, relax substantially via a nonradiative process. Such nonradiative transitions are characteristic of the general nonradiative processes in biomolecules described by Bohr and his colleagues, and must be a quite common method of relaxation for electronically excited biomolecules composed of light atoms upto an atomic number of about 30. The reason for this is that the radiationless transition rate in the decay of the excited electronic state is likely to be more prevalent over radiative transition by a few orders of magnitude, if one extends the theory of atomic Auger transition to biomolecules, with vacancies in low-lying electronic states, involving light atoms. However, before extending this analogy, it is important to recognize the different physical situations between Auger processes in atoms and those in biomolecules as noted later.

The distinctive features of the Auger transition in atomic systems and that in biomolecules have some common and some differentiating characteristics, although both involve interaction between two electrons and the transition of one electron from an upper energy level to an empty level whereby this transition energy is taken up by the other participating electron.

Apart from this, the Bio-Auger process is distinct from the IC as discussed in Section 2.3.2.

2.3.1
Distinctive Features of the Auger and the Bio-Auger Processes

Auger transitions in atoms or atomic ions occur usually following an inner shell vacancy caused either by a photo process involving high-energy photons of X- or γ-rays or by collisions between atoms with incident particles such as electrons, protons, or other charged particles or in atom–atomic ion collisions. The incident energies of these projectiles are therefore usually greater than the ionization potentials of ejected electrons of atoms or atomic ions in consideration. In contrast, in biomolecules, the vacancies in electronic states are usually produced by UV radiations having wavelengths of about 200–400 nm (or optical radiation up to 700 nm, if the energy is sufficient to cause a transition between two electron states). The corresponding energies following Eq. (1) lie approximately between 2 and 6 eV in case of the biomolecules. Thus, the energy available for a radiationless Auger-like transition in biomolecules is noticeably lower than that for the usual Auger transitions in atoms and atomic ions.

In contrast, in standard Auger processes involving vacancies in the K shell of atoms or atomic ions, the transition energy, that is, the energy difference between an electron in an atom or in atomic ions in an initial state of the L, M, or higher shells prior to making the transition to the K shell and the electronic energy of the K shell, ranges from a few decades of electron volts to a few decades of kiloelectron volts. This requires a relativistic treatment for atoms heavier than those in the first transition metals in Mendeleev's periodic table.

In the case of the Auger process in atoms, atoms with a hole in a lower electronic state can relax to the ground state by Auger as well as by fluorescence. As shown in Figures 2.2 and 2.3, in light elements, the Auger process dominates, but still there are only two pathways for returning to the original ground state.

In the case of biomolecules exposed to UV or optical radiation, the electronic pathway following resonant absorption, if permitted by the various conservation laws, is likely to be the one depicted in Figure 2.1. An electron from the ground state singlet, S_0, upon absorbing a photon makes a transition to an excited state, S_{ex}, which is also a singlet state. The absorption is usually a dipole one, so there cannot be any change of electronic spin between the two states. The state, S_{ex}, may undergo some vibrational de-excitation emitting appropriate infrared radiation followed by a transition to a triplet state, T_{ex}, by ISC. This triplet state may or may not further decay to another electronic triplet state, T_0, following the emission of infrared vibronic radiation. The biomolecule may, then, return to its original S_0 ground state by radiative transition, which must be forbidden in character, since it involves a triplet to a singlet transition. Such forbidden transitions associated with phosphorescence have long lifetimes, for example, they could be a few seconds in some amino acids as noted in Table 2.1. On the other hand, the excited S_{ex} state can radiatively decay to a lower singlet state, which ultimately returns to the ground state by radiative transition akin to fluorescence in the atomic case.

Thus, the radiative relaxation or de-excitation to the ground state in biomolecules could take multiple paths of fluorescence and phosphorescence, whereas in atoms, the radiative relaxation involves only fluorescence.

The lifetimes associated with fluorescence in atoms and biomolecules could be very different. In light elements, the dominant relaxation pathway to the ground state is the Auger process. In biomolecules, it is now experimentally well established that the dominant relaxation modes to ground state are radiationless transition from an excited singlet (Crespo-Hernandez *et al.*, 2004) as well as triplet to ground states, which, as discussed in the next section, is akin to the Auger process and is due to electrostatic interaction, bare or shielded, between two or multiple electrons.

Thus, the pathways of de-excitation to ground state by the Bio-Auger process are, in principle, also multiple, although one or more particular ones may dominate.

Topological difference between the electronic configurations of biomolecules consisting usually of H, C, N, and O atoms building up the polypeptide protein backbone with aromatic or nonaromatic side-chains with occasionally ligand bonded metallic ions in some cases such as in metalloproteins, and those involved in the Auger process in the atomic case occurring in an atom or atomic ions is another important consideration in any theoretical formulation of the process. Whereas in the latter case, the transition is caused by the interaction between two electrons in the same atom or atomic ion, in biomolecules, it could be the interaction between electrons in different components of the molecules as well as in the same atom. In addition, the interaction involving electrons between two biomolecules in close proximity could lead to an Auger-like transition as is the case discussed in Bohr and Malik (2007).

In the Auger process in atoms, while an electron from a filled upper quantum state makes a transition to an unfilled energetically lower state, the other electron takes up the transition energy and is usually ejected to a continuum state because of the high energies involved. The electron undergoing Auger-like transition in the biomolecule, on the other hand, can impart its transition energy to many degrees of motion. Bio-Auger processes may also occur between states involving the same atomic or molecular constituent of the biomolecule. However, they could occur between electronic states of two different constituents. They could also take place between two biomolecules in close proximity and hence, all these multiple pathways are open and may contribute. In addition, associated with each electronic state, there are rotational and vibrational degrees of freedom, which could play a role in determining the transition rates. The rotational-vibronic states associated with an excited electronic state may have a lower energy than their counterpart associated with the electronic ground state because, the internuclear distance in the excited state is expected to be slightly larger compared to its value in the ground state due to the increased Coulomb repulsion among nuclei. As a result, the moment of inertia associated with the rotational degree of motion in the excited state increases, thus lowering rotational energy. The spring constant associated with the vibronic motion in the excited state is weaker than that in the ground state, resulting in a lower frequency. A part of the energy will have to be spent in replenishing the rotational-vibronic energy difference as an electron makes a transition from an upper to a lower or ground state. This is also the case for electromagnetic decay. Hence, the maxima of fluorescence spectra are expected to shift to longer wavelengths compared to those of the absorption spectra. This seems to be the case in Table 2.1.

Apart from this, the bulk of the transition energy of a few electron volts in Bio-Auger case may be taken up by electronic excitation or bond stretching or, if enough energy is available, in bond breaking or reorientation of biomolecules. (Note, in diatomic molecules, the electronic de-excitation could lead to dissociation, since sufficient energy of the order of a few electron volts is available.) In some cases, electrons may be emitted to the medium in which the biomolecules are embedded. The energy could also be transmitted to change the motion of the protein to which these biomolecules are attached as ligands.

To emphasize the differences in these two cases, these electronic transitions in biomolecules are termed as *Bio-Auger Processes.* The terminology coined as continuum of the Auger Process in Bohr, Jalkanen, and Malik (2005) is a special case of the general phenomenon of the Bio-Auger process.

2.3.2
Bio-Auger Process and Internal Conversion

An excited electronic state could also decay in radiationless fashion by IC. The underlying interaction for IC is the electron-vibronic coupling and hence, it involves the transition of one electron from an excited state to a lower or ground state. This coupling is usually spin independent and hence, IC occurs between either two singlet or two triplet states. In addition, no electron or charge transfer between two or more components of atoms of biomolecules is involved. It has, however, been difficult to quantitatively ascribe a picosecond timescale to this process (Crespo-Hernandez *et al.*, 2004). These characteristics of nonradiative transitions involving IC differ from those associated with Bio-Auger processes.

2.4
Single Orbital Theory of Bio-Auger Process

One may develop a theory of Bio-Auger process in an analogous way as Wentzel's theory of the Auger process, which assumes that both the initial and final wave functions of two electrons involved in transitions can be suitably expressed as an appropriate antisymmetric product of two electronic wave functions to take into account the Pauli principle, requiring that the electrons will return in the right spin state. On the other hand, wave functions of electronic states in biomolecules are likely to be highly correlated. Nevertheless, in the lowest approximations, for example, in tight binding or density functional theory, they are described by a single orbital wave function in the average or mean field generated by electron–electron, electron–nucleus, and nucleus–nucleus interactions. In the following, we discuss the theory of the Bio-Auger process in this approximation.

2.4.1
Wentzel's Analogous Theory in Biomolecules

A biomolecule, being activated by photons of sufficient energy has a hole electronic state in the ground state configuration and an electron in an excited state. The transition probabilities from this state, $\Psi_{\text{ex}} = |i\rangle$, to the original ground state, $\Psi_{\text{g}} = |f\rangle$, are again given by the expression Eq. (6), and in the lowest approximation $H(p)$ may be taken to be the Coulomb interaction between the electronic states.

Within the context of a density functional description of biomolecules, the electronic orbitals associated with these two states are Kohn–Sham's effective single particle orbitals (Kohn and Shams, 1965) that describe electronic motion in an average field generated by electrostatic attractions between a particular electron and all atomic nuclei and electrostatic repulsion generated by the interaction among all electrons and among all nuclei. Taking a particular nucleus as the reference point, electronic orbitals in the lowest approximation can be described by hydrogen-like orbitals with an effective charge, Z(eff). In that situation, a nonradiative transition from the state Ψ_{ex} to the ground state Ψ_{g} can be triggered by the electrostatic interaction between two electronic states associated with these two configurations. Unlike the Auger transition in atoms, the complete wave function in each of these states is not simply an electronic one, but in the Born–Oppenheimer approximation is the following:

$$\begin{aligned}\Psi_{\text{ex}}&[\varphi_{\gamma}(\text{el})\Phi_{\gamma}(\text{vib-rot})\Phi_{\gamma}(\text{sym})]\\ &\times[\varphi_{\delta}(\text{el})\Phi_{\delta}(\text{vib-rot})\Phi_{\delta}(\text{sym})]\\ &\equiv \varphi_{\gamma}(\text{el})\varphi_{\delta}(\text{el})C_{\gamma}D_{\delta} \qquad (20)\end{aligned}$$

$$\Psi_g[\varphi_\alpha(\text{el})\Phi_\alpha(\text{vib-rot})\Phi_\alpha(\text{sym})] \times [\varphi_\beta(\text{el})\Phi_\beta(\text{vib-rot})\Phi_\beta(\text{sym})] \equiv \varphi_\alpha(\text{el})\varphi_\beta(\text{el})A_\alpha B_\beta \quad (21)$$

$\varphi(\text{el})$, $\Phi(\text{vib-rot})$, and $\Phi(\text{sym})$ in each of the four states refer, respectively, to the electronic, vibrational-rotational, and any special symmetry function of these states. The vibronic-rotational and symmetry wave functions and their specific characteristic parameters, for example, vibrational frequency (or spring constants) and moment of inertial parameter characteristic of internuclear distance associated with each of the electronic states are, in principle, different in the initial and final states.

The electrostatic interaction acting between the two electronic states initiates a nonradiative transition with a half-life of $\tau(\text{non-R})$, which, following Wentzel, is expected to be nearly independent of $Z(\text{eff})$ (actually it should be weakly dependent) and is about 10^{-15} second. However, it is to be multiplied by an overlap matrix. Thus,

$$\tau(\text{non-R}) \cong (10^{-15}\,\text{s})|(A_\alpha B_\beta, C_\gamma D_\delta)|^2 \quad (22)$$

On the other hand, radiative half-lives from the excited to the ground state depend on the energy difference, E, multipolarity, k, and effective charges of the two states; but in case these effective charges are nearly equal, the half-life of the radioactive process $\tau(R)$ is

$$\tau(R) = f(E,k)Z(\text{eff})^4|(A_\alpha B_\beta, C_\gamma D_\delta)|^2 \quad (23)$$

$f(E,k)$ is noted in Section 2.2.2. As noted by Wentzel, for dipole-like transition, and for excitation of a few electron volts

$$\tau(R) \cong (10^{-9}\,\text{s})Z(\text{eff})^4|(A_\alpha B_\beta, C_\gamma D_\delta)|^2 \quad (24)$$

In the strictest sense, for radiative transitions the overlap integral involves only two vibronic states, for example, $|(A_\alpha, C_\gamma)|^2$ since $(B_\beta, D_\delta) = 1$. However, overlooking this difference, one gets the following relation:

$$\tau(\text{non-R})/\tau(R) \cong 10^6 Z(\text{eff})^{-4} \quad (25)$$

The maximum value of effective charge could be as large as ‘6’ for an electron in valence shell of 0; in that case, the nonradiative process is a million times faster. Even for an effective charge of (0.1), the nonradiative decay process is a hundred times faster. Since a typical radiative transition probability is about 10^{-9} second, the nonradiative half-lives are expected to be in the range of pico- to femtoseconds. Thus, the half-life associated with the nonradiation process in biomolecules is expected to be from pico- to femtoseconds, which is much faster than the corresponding half-lives for radiative transitions.

2.4.2
Theory of Nonradiative Decay in Mean Field Approximation in Biomolecules

Following the nonrelativistic theory of the Auger process in atoms, one can develop a theory of nonradiative relaxation in mean field approximation as done in Bohr, Greissen and Malik (2008). A mean field theory of radiationless transitions in biomolecules is to incorporate the following situations:

1. radiationless transitions within a particular atomic constituent of a biomolecule;
2. radiationless transitions caused by a pair of electrons from two different atomic or ionic constituents of a

biomolecule, or two biomolecules in close proximity;
3. the interaction causing the transition may not be a bare electrostatic one but a dressed or shielded one
4. the overall transition rate is to be multiplied by the overlap integral as in Eq. (22).

In addition, unlike the Auger process, an electron may not necessarily be ejected out of an atom or ion, but may be promoted to a higher unoccupied state permitted by the energy conservation; cause the change in bond structure or disruption of a bond or even dissociation; or be transmitted to protein motion in which the biomolecule is embedded. The cases where an electron is either ejected or promoted to a different electronic orbit can be dealt with within the basic theory of the Auger process noted under Section 2.2.1 with appropriate modifications.

The most important modification would be to identify single particle orbitals, φ_α, φ_β, φ_γ, and φ_δ with Kohn–Sham orbitals (Kohn and Shams, 1965) in the density functional approach. In addition, the origin of the coordinate system is to be carefully delineated. The interaction between two interacting electrons may not be a bare Coulomb interaction, but could be modified. Notwithstanding that, $H(p)$ is to be a function of relative distance, r_{ij}, due to the Galilean invariance. Thus, the general form of H_p is

$$H_p = \nu(r_{ij}) \tag{26}$$

One can expand $\nu(r_{ij})$ in Legendre polynomial of the angle between r_i and r_j, θ_{ij}. Any such $\nu(r_{ij})$ can be expanded in spherical harmonics $v(r_{ij}) = \sum_k v_k(r_i, r_j) P_k(\cos\theta_{ij})$, where $v_k(r_i, r_j) = (2k + 1)/2 \int v(r_{ij}) \ P(\cos\theta_{ij}) \ d(\cos\theta_{ij})$. Using the addition theorem one gets

$$v(r_{ij}) = \sum_{k,m} \left(\frac{4\pi}{2k+1}\right) v_k(r_i, r_j) \times Y^*_{km}(\theta_i\varphi_i) Y_{km}(\theta_j\varphi_j) \tag{27}$$

The origin of the coordinate system is to be chosen to be the same as the one used to determine the orbitals.

The matrix element of the transition in the L–S coupling is still given by Eq. (12), except the radial integration is

$$R_k(\alpha, \beta, \gamma, \delta) = \int_0^\infty dr_i \int_0^\infty dr_j P_{n_\alpha \ell_\alpha} \times (r_i) P_{n_\beta \ell_\beta}(r_j) v_k(r_i, r_j) \times P_{n_\gamma \ell_\gamma}(r_j) P_{n_\delta \ell_\delta}(r_i) \tag{28}$$

Thus, the transition rate is given by

$$T(i \to f) = (2\pi/\hbar)|(f|H_p|i)|^2 \rho_f \times |(A_\alpha B_\beta, C_\gamma D_\delta)|^2 \tag{29}$$

As noted earlier, in analyzing the overlap integral, one may take some simple clues from diatomic molecules. In these molecules the vibrational frequency is $f \approx \sqrt{k/\mu}$, where k and μ are, respectively, the spring constant and reduced mass. The potential surfaces of the harmonic oscillator idealizing the vibration in the ground and excited states could be different and in excited states it is likely to be much less steeper. Thus, the spring constant in the excited state is softer than that in the ground state – hence, the vibrational energy quanta in excited states could have less energy compared to that in ground state. Similarly, if the internuclear distance in the excited state becomes larger than that in the ground state, the moment of inertia of the excited state could become larger than that in the ground state, resulting in a lower rotational frequency. In that case, a part of the relaxation energy of an electron as it makes a transition to the ground state is to be imparted to increase the vibrational and rotational frequencies.

A possible way to improve on the Born–Oppenheimer approximation is to expand Ψ_{ex} in Eq. (20) and Ψ_g in Eq. (21) in a complete set of the electronic and vibrational-rotational wave function and also to introduce an electronic-vibrational-rotational coupling.

2.5
Bio-Auger Process and Charge or Electron Transfer

Quite frequently, a Bio-Auger process could result in charge or electron transfer in biomolecules, among its constituent atoms or molecules. To illustrate that, let us consider a biomolecule, $(A(S_0), B)$, with two constituents A and B. Upon absorbing a photon, it could go to an excited state, $(A(S_i), B)$, where S_i is an excited singlet state in A. Bio-Auger relaxation of this molecule could lead to $(A(S_0, S_j), B)$ where an electron is promoted to an excited orbital S_j as the other electron makes a transition to the ground state. In case S_j is a continuum state, one is left behind with $(A^+(S_0), B)$.

An alternative pathway is for $(A(S_i), B)$ to transfer an electron to an excited singlet or triplet orbital, $B(S_j)$ or $B(T_j)$ in B and the partner electron to ground or a lower excited state $A(S_0)$ or $A(S_n)$ of A, that is,

$$\begin{aligned}(A(S_i), B) \xrightarrow{BA} & (A^+(S_0)B^-(S_j)) \\ & \text{or } (A^+(S_0)B^-(T_j)) \\ & \text{or } (A^+(S_n)B^-(S_j)) \\ & \text{or } (A^+(S_n)B^-(T_j))\end{aligned} \tag{30}$$

where BA stands for Bio-Auger process, similar to ISC involving two constituents. Any one of the molecules could return to ground state $(A(S_0), B)$ by the Bio-Auger process by either emitting an electron or transmitting it to other components.

In case enough energy is available, a chain of charge exchange processes of the following type could occur

$$\begin{aligned}h\upsilon + (ABCD\ldots) &\rightarrow (A^*BCD\ldots) \\ &\rightarrow (A^{*+}B^{*-}CD\ldots) \\ &\rightarrow (A^{*+}B^*C^{*-}D\ldots) \\ &\rightarrow (A^*B^{*+}C^{*-}D\ldots) \\ &\rightarrow (A^*B^{*+}C^*D^-\ldots)\end{aligned} \tag{31}$$

Here $(ABCD\ldots)$ are constituent atoms or molecules, and * refers to an excited singlet or triplet state.

In particular any one of the charge transferred excited states could emit an electron in the medium, for example,

$$(A^{*+}B^{*-}CD\ldots) \rightarrow (A^{*+}B^*CD\ldots) + e \tag{32}$$

or transfer the energy to other degrees of freedom. It is to be noted that these states created by charge transfer could act as dipoles, which, by vibration, are capable of emitting EMR.

2.6
Experimental Evidence

In contrast to ascribing radiationless phenomena to vibronic processes (Lim, 1997; Avouris, Gilbert, and El-Sayed, 1977; Callomon, Perkin, and Lopez-Dalgado, 1972; Englman and Jortner, 1970; Jortner, Rice, and Hochstrasser, 1969; Bixon and Jortner, 1968, 1969; Siebrand, 1967) and/or proximity effect (Lim, 1997, 1986), a new aspect, namely the Bio-Auger process, leading to radiationless relaxation in excited biomolecule, is discussed herein. In reality, according to the principle of quantum physics, all these processes compete with each other and depending on various conservation laws such as energy, spin, and symmetry, one or the other may be dominant. In a de-excitation process, all of them compete with radiative transitions if permitted by the conservation laws. The characteristics of a Bio-Auger process are that (i) it can occur between singlet and singlet; singlet and triplet; and triplet and triplet states, (ii) in most cases, it resembles a charge transfer process, (iii) it is a fast process, the transition time being of the order of pico- to femtoseconds, and (iv) the transition energy can be distributed to various degrees of motion, such as electronic excitation, change in bond structures, for example, stretching or breaking, change in molecular orientation, or change in kinetic of the protein in which it is embedded, and so on.

2.6.1
Radiationless De-Excitation from Singlet and Triplet States

As noted in the review article DiBartolo (1980), the evidence pointing to radiationless transition is inferred from the fact that the yields from radiative transitions observed in photoprocesses are quite often less than unity, pointing toward the existence of other nonradiative decay modes. It is now well established that many simple aromatic and nonaromatic (McGlynn, Azumi, and Kinoshita, 1969; Lin, 1980; Schwoerer and Wolf, 2005; DiBartolo, 1980; Karplus and Porter, 1970; Henry and Kasha, 1968; Maki and Zuclich, 1975; Pappalardo, 1980) biomolecules such as amino acids, after absorbing radiation decay via fluorescence and phosphorescence, and the total yield of them are quite often less than the amount absorbed. Thus, the radiationless process is an important relaxation path in biomolecules and since some of these fluorescence rates are in the micro- to nanosecond region, the radiationless decay rates are faster than nanoseconds.

Radiative resonant absorption in biomolecules and in carbonyl compounds occurs in the 200–400 nm range, which corresponds to about 2.0–6.0 eV in excitation energy. Calculated excited energy levels of thymine using time-dependent density function theory with the hybrid B3LIYP taken from Bohr, Jalkanen, and Malik (2005) are noted in Table 2.2.

These are obtained by calculating the ground state configuration and then the appropriate energy difference between the highest occupied and the lowest unoccupied molecular orbitals. Clearly, there are a number of electronic states that could be photoexcited by laser emitting 250–300 nm radiation. It is interesting to note that the triplet excited states lie below the corresponding singlet state, thereby conforming to Hund's rule.

Theoretical calculations using multiconfigurational self-consistent field approach done by Park, Feenstra, and Zeweil (2006), and noted in Table 2.3, confirm the existence of singlet and triplet excited states in benzaldehyde and acetophene in a few electron volts excited region.

The fact that all three amino acids, tryptophan, tyrosine, and phenylalanine exhibit phosphorescence is indicative of the fact that following resonant absorption that can only excite the singlet

Tab. 2.2 Energies in electron volts of the first three electronic excited singlet and triplet states for thymine calculated at the B3LYP level of density functional theory (Bohr, Jalkanen, and Malik, 2005).

Electronic states in thymine	Energy (eV)	Transition wavelength (nm)
First excited singlet	3.8458	322.39
Second excited singlet	4.3019	288.21
Third excited singlet	4.4112	281.06
First excited triplet	3.3046	375.19
Second excited triplet	3.3477	370.36
Third excited triplet	3.8458	322.39

Tab. 2.3 Experimental, Expt, and theoretical calculations in multiconfiguration self-consistent field approximation, Thy, of first few singlet S_0, S_1, and S_2 and triplet states T_1, T_2, and T_3 in benzaldehyde and acetophene noted in (cm^{-1}) units, taken from Park, Feenstra, and Zeweil (2006) (1 cm^{-1} is equivalent to 1.234×10^{-4} eV)

	Benzaldehyde		Acetophene	
	Expt	Thy	Expt	Thy
S_0	0	0	0	0
S_1	26 921	26 541	27 279	–
S_2	35 191	35 978	35 402	36 074
T_1	25 183	24 844	25 791	25 556
T_2	–	24 821	–	25 102
T_3	–	–	–	36 361

ground states of these biomolecules to an excited singlet state, these singlet states make transitions to triplet states by ISC. These states must then partially decay to ground state by nonradiative processes, because at room temperature the total fluorescence and phosphorescence yields are much less than 100%.

The existence of nonradiative decay processes between two singlet states has now been established in many cases. For example, in bacteriorhodopsin, an excited S_n state decays to the first excited S_1 state by a nonradiative process and it is fast (Logunov *et al.*, 2001).

2.6.2
Radiationless Transitions and Electron Transfer in a Protein Complex in Photosynthesis

Zigmantas *et al.* (2002) have also reported a very fast 50–300 fs radiationless decay of the second excited S state to the first excited S state, which they ascribe to IC caused by electronic-vibronic coupling. However, as noted in Crespo-Hernandez *et al.* (2004), such interpretation for these fast transitions could be problematic. These fast rates are, however, characteristic of the Auger process in atoms.

Zigmantas *et al.* (2002) exposed a PCP complex to blue–green light, exciting the ground state, S_0, of peridinin to its second excited S_2 state, which then decays to the first excited S_1 state as well as transfers charge to an excited state, Q_x, in chlorophyll-*a* (chl-*a*). Direct excitation to S_1 state is not allowed by symmetry mismatch. This S_1 state not only relaxes to S_0 by radiationless transition but also causes a charge transfer to Q_y state in (chl-*a*). To accommodate this, they invoked the excitance of an admixture of special state termed *intramolecular charge transfer* (ICT) *state* with S_0.

In the context of the Bio-Auger process, the ICT and nonradiative decay go hand-in-hand. The electronically excited S_2 state, interacting with an adjacent electron, under the theory of the Bio-Auger process, could undergo nonradiatively to both S_1 and S_0 and transfer an electron to all states of (chl-*a*) if allowed by energy conservation laws (Bohr and Malik, 2008). Thus, the decay process for the $S_2 \rightarrow S_1$ transition produces simultaneously an electron transfer to both Q_x and Q_y states of (chl-*a*) and a nonradiative de-excitation to S_1, as shown in Figure 2.4. It is noteworthy that the decay rates for both processes are noted to be about 200 fs for the former case and 50–300 fs for the latter case in Zigmantas *et al.* (2002), that is, they could be equal, as it should be if they occur simultaneously. S_2 can also decay to S_1 by EMR. Thus, the total decay width $\Gamma_T(S_2)$ is a sum of the decay widths $\Gamma(BA : S_2 \rightarrow Q_x)$, $\Gamma(BA : S_2 \rightarrow Q_y)$, and $\Gamma(R : S_2 \rightarrow S_1)$

$$\Gamma(S_2) = \Gamma(BA : S_2 \rightarrow Q_x) + \Gamma(BA : S_2 \rightarrow Q_y) + \Gamma(R : S_2 \rightarrow S_1) \quad (33)$$

In Eqs (33) and (34), BA and R refer, respectively, to Bio-Auger and radiative transitions. The relation among corresponding half-lives, $T_T(S_2)$, $T(BA : S_2 \rightarrow Q_x)$, $T(BA : S_2 \rightarrow Q_y)$, and $T(R : S_2 \rightarrow S_1)$ is the following

$$\frac{1}{T_T(S_2)} = \frac{1}{T(BA : S_2 \rightarrow Q_x)} + \frac{1}{T(BA : S_2 \rightarrow Q_y)} + \frac{1}{T(R : S_2 \rightarrow S_1)} \quad (34)$$

Since $T(R : S_2 \rightarrow S_1)$ is expected to be much larger than the other two, the total half-life is essentially determined by the two half-lives associated with the Bio-Auger process transferring electrons to chl-*a*.

Once populated, S_1 could also relax by the Bio-Auger process transferring an electron to (chl-*a*) and simultaneously de-exciting nonradiatively to S_0. In that case, it would be unnecessary to invoke the idea of a charge transfer state mixed with S_1. One may also note that a component of Bio-Auger decay could retransfer an electron to S_2 if allowed energetically, which might appear as a misleading admixture of S_2 in S_1. The process is summarized schematically in Figure 2.4.

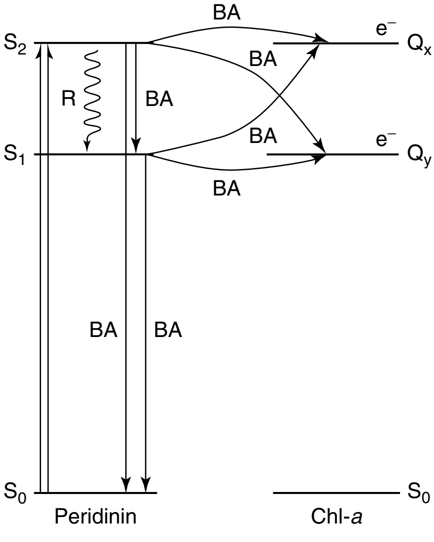

Fig. 2.4 Pathway of charge transfer from peridinin to chl-*a* in the PCP complex by a Bio-Auger process. Because of symmetry forbiddenness, direct transition of S_0 to S_1 by photo absorption cannot occur. Photoabsorption excites S_0 to S_2. S_2 state can undergo a Bio-Auger (BA) transition transferring an electron to Q_x and Q_y, if allowed by selection rules, and at the same time decay to S_1 by radiative IC processes (R). S_1 cannot decay to S_0 by a radiative process because of symmetry forbiddenness (it could probably decay weakly), but S_1 can undergo a BA transition transferring an electron to Q_x and Q_y and at the same time decay to S_0. The net result is a transfer of two electrons from peridinin to chl-*a*.

In short, following blue–green resonant absorption in PCP, exciting it directly to the second excited S_2 state, two electrons from peridinin could be transferred to (chl-*a*) component as S_2 relaxes to S_0 via S_1 and one has a (PCP) compound with a two-electron hole (i.e. the equivalent of two-positive charge) in peridinin and two-negatively charged (chl-*a*). This is a dipole, which, if it vibrates, could, of course, transfer its energy to its surroundings by emitting EMR or transfer two electrons to other molecules by transportation.

2.6.3
Dark Structure

The above analysis indicates that a biosystem undergoing electronic excitation could relax both electromagnetically and by a Bio-Auger process. In the latter case, it could in many instances be accompanied by intra- and intermolecular electron transfer. Such changes in the electronic configurations could lead to the change in the bond structure including rupture. The process is expected to take place in the pico- to femtosecond timescale. Such electron transfers and changes in molecular structure are consistent with the investigations in Wan *et al.* (1999, 2000) and Fiebig *et al.* (1999). The dark structure reported in Srinivasan *et al.* (2005) that accompanies radiationless transitions is the manifestation of these electronic transfers.

2.6.4
Exposures to Ultraviolet Radiation and Relaxation

Human beings and many other animals are being constantly exposed to the UV and blue optical radiation of sunlight. The energy of a few electron volts associated with these radiations, calculated using Eq. (1), is capable of electronic excitation in the biomolecules of exposed organic tissues. Experimentally, almost all of these tissues do not relax to ground state by emitting light or UV radiation, but they do relax and relax fast, since after being exposed to the sun, most animals including human beings do not glow and their skin remains intact. This relaxation is a radiationless process but cannot be thermal because 1-eV excitation is equivalent to about 10 500 K. The relaxation via a Bio-Auger process is a distinct possibility because it is fast and the energy of one electron could easily be transferred to the environment or the motion of the protein in which these molecules are embedded or attached to. The failure of these molecules to relax back to their original state could then inhibit the normal function of the host proteins leading to abnormal behaviors or cancer.

2.6.5
Bio-Auger Process Involving Intermolecular Electronic States

A Bio-Auger process is not restricted to electrons belonging to the same molecules or different molecular constituents of a complex biomolecule. It can occur between two electronic states in different molecular complexes in close proximity. In fact, the relaxation of the thymine dimer to two monomers in ground states, as it comes in close proximity of the negative ion cofactor, riboflavin, affected by the exposure of the photolyase protein to visible light, has been attributed to the Bio-Auger process

(Bohr, Jalkanen, and Malik, 2005; Bohr and Malik, 2007).

DNA nucleotides, for example thymine, being exposed to UV radiation of 200–300 nm lead to dimerization by causing a lesion between two adjacent nucleotides, in most cases forming a cyclobutane pyrimidine dimer (CPD) or duplex. This perturbic structure creates a kink in the helical axis of DNA leading to errors in genetic codes, which ultimately could lead to carcinogenetic behaviors. Very interestingly, this defect is repaired when the dimer comes in the proximity of photoactivated photolyse protein by optical radiation of 350–500 nm. The dimer coming in contact with this photoactivated photolyse is detached into two separate monomers in their ground states.

Density functional theoretical calculation indicates a number of excited triplet and singlet states of pyrimidine in the 3.5- and 5.0-eV excitation energy intervals as noted in Table 2.2. Resonant absorption of UV radiation would allow thymine to undergo a Frank–Condon transition to an excited S state, which after some vibronic de-excitation can cross over to a triplet state by ISC, also forming a duplex. Such a state is usually long lived and can be characterized as an isomeric state. Analogous states have also been identified in the photolysis of relatively simple polyatomic molecules such as formaldehyde (Moule and Walsh, 1975) and glyoxol (Tayer and Yardley, 1974). The energy of the dimer is less than the energy of the corresponding excited states of two monomers because of the radiative emission from the vibronic de-excitation.

Photolyase protein being exposed to optical radiation excites 7,8-didemethyl-8-hydroxy-5-deazariboflavin ($(FADH^-)$) cofactor to $(FADH^-)^*$, as discussed in Sancar (2003) and Sancar (1994). This excited negatively charged $(FADH^-)^*$ upon coming in proximity with the thymine dimer (which is actually in a hole excited state) interacts electrostatically by the Bio-Auger process leading an electron to make a transition to the ground state of thymine, thereby, detaching the dimer and in the process, de-exciting the cofactor to ground state, that is, to (FADH). The experiment of Mees *et al.* (2004) does indicate that (i) the thymine dimer is in a metastable state, (ii) a structural change in the stretch of damaged DNA containing the dimer exists, implying a change of electronic structure of the dimer compared to that of two monomers, (iii) a direct involvement of electrons in the detachment process of the dimer, and (iv) the detachment occurs only when $(FADH^-)^*$ formed in the exposure of photolyse protein to visible light, appears in the vicinity of the dimer.

Thus, the experimental analysis supports the theoretical picture. Furthermore, Mees *et al.* (2004) found that the repair process occurs in a time scale of about 10^{-10} second. The theoretical calculation of Bio-Auger transition rate done in the Bethe–Heitler approximation Eq. (13) agrees with this rate (Bohr and Malik, 2007).

Acknowledgments

The authors are thankful for the assistance of Mr Benedict Schurwanz and Mr M. Suhel Sabra in the preparation of the manuscript and figures, respectively. HGB is deeply appreciative of the grant from Danish Foundation for Quantum Protein Centre.

3.1
Introduction

Organisms have evolved a wide variety of mechanisms to use and respond to sunlight. In many cases, the biological response is mediated by structural changes that follow photon absorption in the biomolecule. Exposure to high-energy photons, however, can cause irreversible damage in biological matter or even alter the genetic information. Despite the relevance of these photochemical processes in biology, little is known about the atomistic mechanisms by which irradiation can bring about changes in the chemical structure. Understanding these photobiological reactions requires insight into the underlying ultrafast molecular dynamics, which typically occur at femto- to picosecond timescales ($10^{-15}-10^{-12}$ s). As the relevant time and spatial resolutions are notoriously hard to access experimentally, computer simulations have become an essential tool to enhance our understanding of photobiological processes. Furthermore, the insights acquired by computation may be used directly to design artificial devices that mimic biological function. In this chapter, we first review the general theoretical framework that underlies our current understanding of photochemical reactions. Then we present how these theoretical concepts can be employed in practical simulation protocols. Finally, we discuss a number of representative applications, where such protocols have been used to elucidate the mechanisms of important photobiological processes.

3.2
Observing Excited State Dynamics on a Computer

The size and complexity of a typical biomolecular system, together with the timescales that must be reached, necessitates the use of classical molecular dynamics for the nuclear degrees of freedom in conjunction with a Molecular Mechanics force field. In molecular dynamics simulations, Newton's equations of motion are solved to obtain a trajectory of the dynamics of a molecule over a period of time, starting from an X-ray or nuclear magnetic resonance (NMR)-derived structure. To model the electronic rearrangement upon photon absorption, a quantum mechanical description is required for those parts of the system that are involved in the reaction. For the remainder, a

ISBN: 978-3-527-40702-6

simple molecular mechanics force field model suffices. Both models are combined in a hybrid quantum mechanical/molecular mechanics (QM/MM) scheme. As schematically shown in Figure 3.1, a photochemical reaction starts in the excited state but ends in the ground state after radiationless decay via a conical intersection. To model the deactivation process, surface-hopping schemes are employed in the molecular dynamics (MD) simulations. We now present the theoretical foundations that provide the basis for computer simulations of excited state dynamics in complex biological molecules.

3.2.1
Born–Oppenheimer Approximation

All matter consists of nuclei and electrons that have a positive and negative charge, respectively. Electrostatic forces keep these particles together to form molecules of any size and complexity. The Schrödinger equation provides the mathematical description of the behavior of such many-body systems:

$$H\Psi = E\Psi \tag{1}$$

In this eigenvalue equation, H is the system's Hamilton operator, or Hamiltonian, which returns the total energy E of the system when operating on the many-body wave function Ψ. As in classical mechanics, the Hamiltonian is defined as the sum of the kinetic T and potential energy V:

$$H = T + V \tag{2}$$

From the wave function Ψ, all static properties of the system of interest can be derived. Dynamic information is obtained by integrating the time-dependent Schrödinger equation:

$$i\hbar\frac{\partial}{\partial t}\Psi = H\Psi, \tag{3}$$

with $\hbar$ the Planck constant divided by 2π. Unfortunately, an exact solution exists only if there are at most two interacting particles in the system, such as for instance the hydrogen atom. Solving the equations for any larger system requires approximations.

The first approximation is to ignore relativistic effects. Only for very heavy elements, which have very high nuclear charges, the inner shell electrons can move so fast that relativistic effects become important. Since biological molecules are mostly composed of first and second row elements, the electronic velocities are sufficiently low for

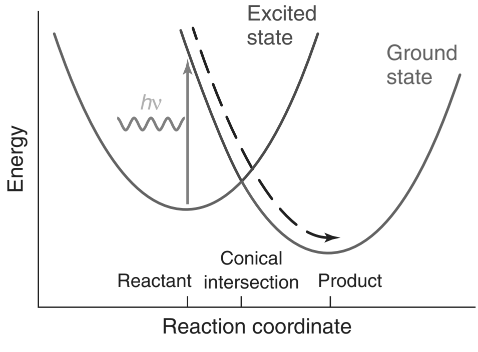

Fig. 3.1 One-dimensional scheme of a photochemical reaction. After photon absorption (cyan arrow), evolution takes place on the excited state potential energy surface (red), until the system hits the conical intersection. At the intersection, a radiationless transition to the ground state occurs (green). After the decay, the system continues evolving in the ground state. (Please find a color version of this figure on the color plates)

relativistic effects to be ignored. Within this approximation, the nonrelativistic Hamiltonian is given by

$$H = T_N + T_e + U(\mathbf{r}, \mathbf{R}) \tag{4}$$

where T_e and T_N are the operators of the kinetic energy of the electrons and the nuclei, respectively, and $U(\mathbf{r}, \mathbf{R})$ is the total potential energy of the electrons and nuclei together. Since relativistic effects are ignored, no spin interactions are included in the Hamiltonian. The vector **r** denotes the set of electronic coordinates and the vector **R** stands for the nuclear coordinates.

The next approximation is to separate the motion of the electrons from that of the nuclei. This so-called Born–Oppenheimer approximation provides the basis for modern quantum chemistry. The approximation rests on the mass difference between electrons and nuclei. Nuclei are much heavier than electrons, so that the latter adopt instantaneously to displacements of the former. Electrons "see" nuclei standing still, whereas the nuclei move on potential energy landscapes created instantly by the faster electrons. Within the Born–Oppenheimer approximation, the electronic and nuclear wave functions can be treated independently.

First, the Schrödinger equation is solved for electrons moving in a framework of fixed nuclei. Thus, the nuclear kinetic energy (T_N) is dropped from the full Hamiltonian (Eq. (4)) to yield

$$H^e = T_e + U(\mathbf{r}, \mathbf{R}) \tag{5}$$

where the superscript e indicates the *electronic* Hamiltonian. The electronic wave functions are the eigenfunctions of this Hamiltonian

$$H^e \psi_i(\mathbf{r}; \mathbf{R}) = V_i(\mathbf{R}) \psi_i(\mathbf{r}; \mathbf{R}) \tag{6}$$

with $\psi_i(\mathbf{r}; \mathbf{R})$ and $V_i(\mathbf{R})$ the electronic wave functions and their electronic energies, respectively, both of which depend *parametrically* on the nuclear coordinates. The wave functions are the adiabatic electronic states, representing the electronic ground state ($i = 0$), excited state ($i = 1$), second excited state ($i = 2$), and so on. How these wave functions are obtained in practical computations is the subject of modern quantum chemistry (Szabo and Ostlund, 1989) and is briefly discussed in Section 3.2.3.2.

The adiabatic wave functions can be made *orthonormal*, that is,

$$\langle \psi_i | \psi_j \rangle = \int_{-\infty}^{\infty} \psi_i(\mathbf{r}; \mathbf{R})^* \psi_j(\mathbf{r}; \mathbf{R}) d\mathbf{r} = \delta_{ij} \tag{7}$$

where the Dirac bra-ket notation ($\langle | \rangle$) has been introduced that is used throughout the text and where δ_{ij} is the Kronecker delta-function, which is 1 if $i = j$ and 0 otherwise.

Within the Born–Oppenheimer approximation, the adiabatic electronic states provide a complete basis to expand the molecular wave function in

$$\Psi(\mathbf{r}, \mathbf{R}) = \sum_j \chi_j(\mathbf{R}) \psi_j(\mathbf{r}; \mathbf{R}) \tag{8}$$

where the expansion coefficients $\chi_j(\mathbf{R})$ are the nuclear wave functions. Substituting the expression for the molecular wave function in the time-independent Schrödinger equation (Eq. (1)) and multiplying by the adiabatic electronic wave function $\psi_i^*(\mathbf{r}; \mathbf{R})$ from the left, followed by integration over the electronic coordinates **r** leads to the following set of coupled equations:

$$\sum_j H_{ij}(\mathbf{R}) \chi_j(\mathbf{R}) = E(\mathbf{R}) \chi_i(\mathbf{R}) \tag{9}$$

with

$$H_{ij}(\mathbf{R}) = \langle \psi_i(\mathbf{r};\mathbf{R})|H|\psi_j(\mathbf{r};\mathbf{R})\rangle = \langle \psi_i(\mathbf{r};\mathbf{R})|T_N|\psi_j(\mathbf{r};\mathbf{R})\rangle + V_i(\mathbf{R})\delta_{ij} \quad (10)$$

The nuclear kinetic energy operator is defined as

$$T_N = -\sum_k \frac{\hbar^2}{2M_k}\nabla^2_{\mathbf{R}_k} \quad (11)$$

where M_k is the mass of nucleus k, and the sum runs over all nuclei. Using this relation, Eq. (10) can be rewritten as (Köppel, Domcke and Cederbaum, 1984)

$$H_{ij}(\mathbf{R}) = [T_N + V_i(\mathbf{R})]\,\delta_{ij} - \Lambda_{ij}(\mathbf{R}) \quad (12)$$

The *nonadiabatic* operator elements $\Lambda_{ij}(\mathbf{R})$ are defined as

$$\Lambda_{ij}(\mathbf{R}) = \sum_k F^k_{ij}(\mathbf{R})\nabla_{\mathbf{R}_k} + G_{ij}(\mathbf{R}) \quad (13)$$

$$F^k_{ij}(\mathbf{R}) = \frac{\hbar^2}{M_k}\langle \psi_i(\mathbf{r};\mathbf{R})|\nabla_{\mathbf{R}_k}|\psi_j(\mathbf{r};\mathbf{R})\rangle \quad (14)$$

$$G_{ij}(\mathbf{R}) = \sum_k \frac{\hbar^2}{2M_k}\langle \psi_i(\mathbf{r};\mathbf{R})|\nabla^2_{\mathbf{R}_k}|\psi_j(\mathbf{r};\mathbf{R})\rangle \quad (15)$$

In contrast to H^e (Eq. (5)), where T_N was omitted, H_{ij} is *not* diagonal in the basis of the adiabatic electronic wave functions (ψ_i). The individual electronic states are coupled via nuclear motions. Nonadiabatic coupling is the key player in a photochemical reaction, as shown below.

In the limit that the electronic wave functions vary slowly with the nuclear dynamics, the nonadiabatic operators $F^k_{ij}(\mathbf{R})$ and $G_{ij}(\mathbf{R})$ are vanishingly small and can be safely neglected. Thus, the crux of the Born–Oppenheimer approximation is that H_{ij} is assumed to be diagonal everywhere:

$$H_{ij}(\mathbf{R}) = [T_N + V_i(\mathbf{R})]\,\delta_{ij} \quad (16)$$

With this assumption, the total molecular wave function becomes product of a *single* nuclear and a *single* electronic wave function:

$$\Psi^{\text{tot}}_i(\mathbf{R},\mathbf{r}) = \chi_i(\mathbf{R})\psi_i(\mathbf{r};\mathbf{R}) \quad (17)$$

which implies that nuclear motion takes place on a *single* electronic potential energy surface $V_i(\mathbf{R})$ of a given electronic state i. The Born–Oppenheimer approximation not only reduces the computational complexity of the equations that have to be solved but also provides a conceptually more intuitive picture of molecular structure and dynamics.

3.2.2
Conical Intersections

In regions of configuration space where the energy gaps between electronic states become comparable to the energy gaps between the vibrational states of the nuclei, resonance will occur between nuclear vibrations and electronic transitions. The populations of the adiabatic wave functions become strongly dependent on the nuclear dynamics and the nonadiabatic coupling operator ($\mathbf{\Lambda}$, Eq. (13)) can no longer be neglected. In regions of strong nonadiabatic coupling, the Born–Oppenheimer approximation breaks down, and nuclear dynamics induces population transfer between different electronic states, which is the origin of a radiationless transition. Furthermore, as we will demonstrate in this section, adiabatic potential energy surfaces can even intersect due to the coupling. These crossings provide efficient funnels for radiationless deactivation of the excited state and therefore play a crucial role in photochemistry.

In principle *all* electronic states $\psi_i(\mathbf{r};\mathbf{R})$ are involved in the nonadiabatic coupling. However, in practice, only states that are close in energy couple significantly. Therefore, the set of states included in the coupling can be truncated, thereby reducing the dimension of the nonadiabatic coupling matrix $\mathbf{\Lambda}$.

The nonadiabatic coupling operators Λ_{ij} are nonlocal derivative operators that depend inversely on the energy gap between the coupled adiabatic states (Worth and Cederbaum, 2004):

$$F_{ij}^{k}(\mathbf{R}) = \frac{\hbar^2}{M_k}\langle\psi_i(\mathbf{r};\mathbf{R})|\nabla_{\mathbf{R}_k}|\psi_j(\mathbf{r};\mathbf{R})\rangle = \frac{\hbar^2}{M_k}\frac{\langle\psi_i(\mathbf{r};\mathbf{R})|\nabla_{\mathbf{R}_k}H^e|\psi_j(\mathbf{r};\mathbf{R})\rangle}{V_j - V_i} \tag{18}$$

As the gap $(V_j - V_i)$ narrows, coupling increases and the nuclear wave function that is initially on one surface will spread to another without losing energy, and a radiationless transition occurs.

If the surfaces become degenerate, that is, $V_j - V_i = 0$, the coupling becomes infinite. Owing to the nonlocal nature of the coupling matrix elements in the adiabatic representation, it is convenient to switch to a diabatic representation, in which the nonadiabatic coupling operator becomes a local, potential-like operator. The switch to the diabatic wave functions φ^{dia} is achieved by a unitary transformation of the adiabatic wave functions ψ^{adia} at each point in space (Worth and Cederbaum, 2004):

$$\boldsymbol{\varphi}^{\text{dia}} = \mathbf{S}(\mathbf{R})\boldsymbol{\psi}^{\text{adia}} \tag{19}$$

From now on, we no longer use the superscripts dia and adia to indicate the diabatic φ and adiabatic ψ wave functions. In the diabatic representation, the complete Hamiltonian (Eq. (12)) becomes

$$H_{ij}(\mathbf{R}) = T_N\delta_{ij} + W_{ij}(\mathbf{R}) \tag{20}$$

and the molecular Schrödinger equation (Eq. (12)) can be written in matrix notation as

$$\mathbf{H}\boldsymbol{\chi} = [T_N\mathbf{1} + \mathbf{W}(\mathbf{R})]\,\boldsymbol{\chi} = \mathbf{E}\boldsymbol{\chi} \tag{21}$$

where $\mathbf{1}$ is the identity matrix, $\boldsymbol{\chi}$ the vector of nuclear wave functions (χ_i, Eq. (8)), and $\mathbf{W}(\mathbf{R})$ is the diabatic potential energy matrix, which in contrast to the adiabatic potential matrix $\mathbf{V}(\mathbf{R})$ contains only *local* terms.

To illustrate the concept of the surface crossing, we consider a molecule in which there is coupling between two diabatic states A and B only. We can expand the potential matrix elements in a Taylor series around an arbitrary point $\mathbf{R}_0$:

$$\mathbf{W}(\mathbf{R} - \mathbf{R}_0) = \mathbf{W}^{(0)} + \mathbf{W}^{(1)} + \mathbf{W}^{(2)} + \cdots \tag{22}$$

At $\mathbf{R}_0$, we can choose the diabatic and adiabatic states to be equal. Then, the zeroth-order matrix, $\mathbf{W}^{(0)}$, is a diagonal matrix in which the elements correspond to the energies E_A, E_B of the diabatic states φ_A and φ_B at $\mathbf{R}_0$, which, by our choice of origin, are identical to the *adiabatic* energies V_1 and V_2:

$$\mathbf{W}^{(0)} = \frac{E_A + E_B}{2}\mathbf{1} + \begin{pmatrix} -\frac{E_B - E_A}{2} & 0 \\ 0 & \frac{E_B - E_A}{2} \end{pmatrix} = \mathbf{V}(\mathbf{R}_0) \tag{23}$$

For small displacements $\Delta\mathbf{R}$ around $\mathbf{R}_0$, the Taylor expansion in Eq. (22) can be truncated after the first-order term

$$\mathbf{W}^{(1)} = \frac{\boldsymbol{\lambda} \cdot \Delta\mathbf{R}}{2}\mathbf{1} + \begin{pmatrix} -\frac{1}{2}\delta\boldsymbol{\kappa} \cdot \Delta\mathbf{R} & \boldsymbol{\kappa}^{AB} \cdot \Delta\mathbf{R} \\ \boldsymbol{\kappa}^{AB} \cdot \Delta\mathbf{R} & \frac{1}{2}\delta\boldsymbol{\kappa} \cdot \Delta\mathbf{R} \end{pmatrix} \tag{24}$$

in which we have introduced linear potential constants that are defined as

$$\begin{aligned} \delta\boldsymbol{\kappa} &\equiv \nabla_{\mathbf{R}} \left(E_B - E_A\right)|_{\mathbf{R}_0} \\ \boldsymbol{\kappa}^{AB} &\equiv \nabla_{\mathbf{R}} \left\langle\varphi_A|H^e|\varphi_B\right\rangle|_{\mathbf{R}_0} \\ \boldsymbol{\lambda} &\equiv \nabla_{\mathbf{R}} \left(E_A + E_B\right)|_{\mathbf{R}_0} \end{aligned} \tag{25}$$

We now choose $\mathbf{R}_0$ to be the point of degeneracy, where E_A and E_B are equal. Under this condition, $\mathbf{W}^{(0)}$ becomes a constant that we conveniently set to zero. The adiabatic potential energy surfaces V_1 and V_2 are obtained by diagonalizing the diabatic potential matrix $\mathbf{W}$. Thus for the two-state system considered here,

$$V_{1,2} = \frac{1}{2}\boldsymbol{\lambda} \cdot \Delta\mathbf{R} \pm \frac{1}{2} \times \sqrt{\left[\delta\boldsymbol{\kappa} \cdot \Delta\mathbf{R}\right]^2 + 4\left[\boldsymbol{\kappa}^{AB} \cdot \Delta\mathbf{R}\right]} \tag{26}$$

The necessary condition for a crossing between the two potential energy surfaces at $\mathbf{R}_0$ is that the two electronic energies are identical. Therefore, two conditions need to be fulfilled simultaneously:

$$\begin{aligned} \delta\boldsymbol{\kappa} \cdot \Delta\mathbf{R} &= 0 \\ \boldsymbol{\kappa}^{AB} \cdot \Delta\mathbf{R} &= 0 \end{aligned} \tag{27}$$

Thus, to first order, the degeneracy is lifted in the two-dimensional space spanned by the vectors $\delta\boldsymbol{\kappa}$ and $\boldsymbol{\kappa}^{AB}$, known as the *gradient difference vector* and *derivative coupling vector*, respectively. The space spanned by these two vectors is often referred to as the *branching space*, or *g–h plane*. Furthermore, as is evident from Eq. (26) and illustrated in Figure 3.2, the topology of the surfaces is that of a double cone, with the point of degeneracy at the apex. Orthogonal to the two-dimensional branching space exists the so-called intersection space (or seam space), in which the energies of the two states remain degenerate to first

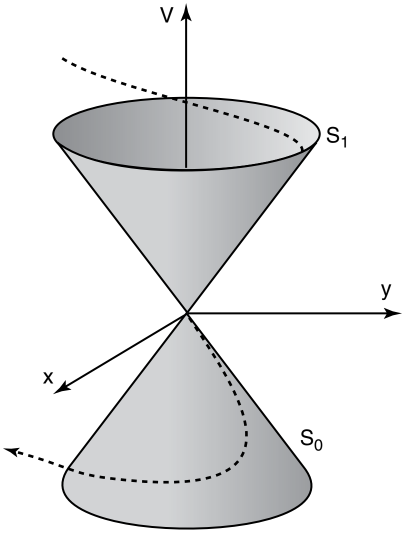

Fig. 3.2 A conical intersection plotted in the two-dimensional branching space that is spanned by the gradient difference vector (*g*) and the derivative coupling vector (*h*). Motion away from the intersection in the *g*–*h* plane lifts the degeneracy between the two electronic states S$_1$ and S$_0$. The dotted line shows a path of a nuclear trajectory passing from one electronic state (S$_1$) to another (S$_0$) through the intersection funnel.

order. In a molecule with N internal degrees of freedom, the intersection space thus forms an $N-2$ dimensional seam, each point of which is a conical intersection. If a molecule has less than two degrees of freedom, the two conditions for degeneracy (Eq. (27)) cannot be simultaneously fulfilled. Therefore in diatomic molecules states of the same symmetry do not cross, as was formulated by von Neumann and Wigner (1929).

The concept of the intersection seam is illustrated in Figure 3.3 for a hypothetical triatomic molecule. In our model system, there are three internal degrees of freedom: two bond lengths (x_1 and x_2) and one angle (α), which are sufficient to define the configuration of the molecule. Since *two* degrees of freedom are required to span the branching space, there is only *one* degree of freedom available to form the intersection seam. In our simple model system we let the branching space coordinates (i.e. the gradient difference and derivative coupling vectors) coincide with the two bond-length variables x_1 and x_2. In reality, the branching space coordinates are usually more complex linear combinations of the three internal degrees of freedom.

The first plot in Figure 3.3 shows the two adiabatic potential energy surfaces (denoted by S_0 and S_1) in the branching space. When projected onto this space, the surfaces adopt a double cone shape with a single intersection point at the apex. Any displacement away from the apex in either the x_1 or x_2 coordinate lifts the degeneracy.

The second plot shows the surfaces in the subspace spanned by the derivative coupling vector x_2 and the third independent degree of freedom, the bond angle α. The gradient difference vector x_1 is kept fixed at the conical intersection. Therefore, the only coordinate that can lift the degeneracy is x_2. If the latter is at the conical intersection as well, the surfaces intersect irrespective of the value of the angle variable (α). The intersection seam is thus a one-dimensional line that is parallel to α.

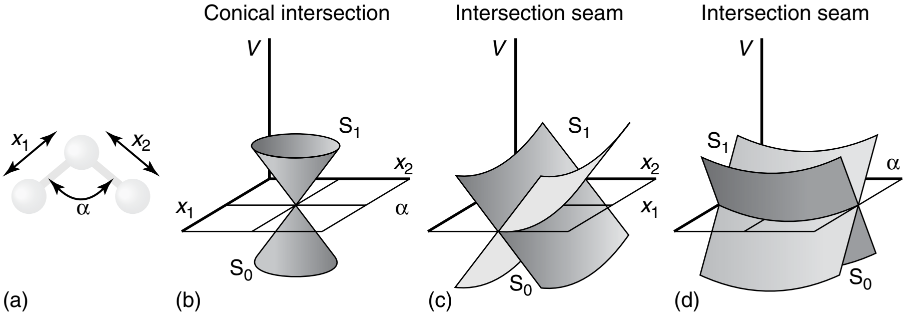

Fig. 3.3 Surface crossing between two potential energy surfaces S_1 and S_0 in a hypothetical triatomic molecule (a). We let x_1 and x_2 be parallel to the gradient difference vector and the derivative coupling vector, respectively, and α be the remaining degree of freedom. When projected onto the branching space spanned by x_1 and x_2, the surfaces of S_0 and S_1 intersect in a single point, the conical intersection (b). In the two other subspaces, spanned by either x_2 and α (c), or by x_1 and α (d), there is an intersection line between the surfaces. In the second plot x_1 and in the third x_2 are assumed to be at their conical intersection coordinates.

The third plot shows the projection of the two surfaces onto the subspace spanned by the gradient difference vector x_1 and the bond angle variable α. The derivative coupling vector x_2 is constrained to be at the conical intersection. Under this condition, only x_1 can lift the degeneracy and the surfaces intersect along a seam parallel to α.

In this idealized example, symmetry arguments could have also been used to illustrate the concept of the conical intersection seam. If x_1 or x_2 become identical, the point group of the molecule changes from C_s to C_{2v}. In the first point group, the electronic wave functions belong to the same irreducible representation, and their surfaces cannot intersect due to symmetry reasons. In the C_{2v} point group, in contrast, the wave functions belong to different irreducible representations, and a crossing is not symmetry forbidden.

The conical intersection has a number of peculiar characteristics that can be exploited in excited state molecular dynamics simulations. If we consider a small displacement $\mathbf{q}$ away from the cone tip in the branching plane, the diabatic energy matrix $U_{A,B}$ becomes

$$\begin{aligned} U_{A,B}(\mathbf{q}) = \begin{pmatrix} H_{AA}(\mathbf{q}) & H_{AB}(\mathbf{q}) \\ H_{AB}(\mathbf{q}) & H_{BB}(\mathbf{q}) \end{pmatrix} &= S(\mathbf{q})\mathbf{1} \\ &+ \begin{pmatrix} -\Delta H(\mathbf{q}) & H_{AB}(\mathbf{q}) \\ H_{AB}(\mathbf{q}) & \Delta H(\mathbf{q}) \end{pmatrix} \end{aligned} \tag{28}$$

with (see Eq. (24))

$$\begin{aligned} \Delta H(\mathbf{q}) &= \frac{H_{BB}(\mathbf{q}) - H_{AA}(\mathbf{q})}{2} = \boldsymbol{\delta\kappa} \cdot \mathbf{q} \\ H_{AB}(\mathbf{q}) &= \boldsymbol{\kappa}^{AB} \cdot \mathbf{q} \\ S(\mathbf{q}) &= \frac{H_{BB}(\mathbf{q}) + H_{AA}(\mathbf{q})}{2} \end{aligned} \tag{29}$$

The matrix $U_{A,B}(\mathbf{q})$ is the two-state Hamiltonian matrix defined in the basis of the eigenvectors at the reference point, $\mathbf{R}_0$, at which the diabatic and adiabatic bases are identical. The diabatic potential matrix $U_{A,B}(\mathbf{q})$ can be diagonalized by the rotation matrix $\mathbf{T}(\mathbf{q})$ (Atchity, Xantheas and Ruedenberg, 1991), to obtain the adiabatic energies $V_{1,2}$

$$\mathbf{T}(\mathbf{q}) = \begin{pmatrix} \cos[\theta(\mathbf{q})] & -\sin[\theta(\mathbf{q})] \\ \sin[\theta(\mathbf{q})] & \cos[\theta(\mathbf{q})] \end{pmatrix} \tag{30}$$

From Eq. (29), the rotation angle $\theta(\mathbf{q})$ is defined as (Atchity, Xantheas and Ruedenberg, 1991; Atchity and Ruedenberg, 1999; Yarkony, 2000; Koppel, Gronki and Mahapatra, 2001; Muller, Koppel and Cederbaum, 1993; Matsika and Yarkony, 2002):

$$\begin{aligned} \theta(\mathbf{q}) &= \frac{1}{2}\arctan\left[\frac{2H_{AB}(\mathbf{q})}{\Delta H(\mathbf{q})}\right] \\ &= \frac{1}{2}\arctan\left[\frac{2\boldsymbol{\kappa}^{AB}\cdot\mathbf{q}}{\boldsymbol{\delta\kappa}\cdot\mathbf{q}}\right] \\ &= \frac{1}{2}\arctan\left[\frac{y}{x}\right] \end{aligned} \tag{31}$$

where we have introduced the *scaled* coordinates x and y. Replacing these scaled coordinates by polar coordinates r and ϕ

$$\begin{aligned} r &= \sqrt{x^2 + y^2} \\ \phi &= \arctan\left[\frac{2y}{x}\right] \end{aligned} \tag{32}$$

yields the following expression for the rotation angle

$$\theta\left(H_{AB}, \Delta H\right) = \frac{\phi}{2} \tag{33}$$

Thus, a simple relationship exists between the polar angle (ϕ), which defines a rotation around the apex of the cone in the branching space on one hand, and the *mixing* angle (θ) for the diabatic states (φ_A, φ_B) on the other. Since the mixing depends *only* on the polar angle ϕ and *not* on the radius r, it is constant along any straight line with the origin at the apex of the double cone.

Because of this relationship, the adiabatic wave function changes sign upon a complete rotation around the apex of the cone in the branching space. This is demonstrated by comparing the wave functions at $\phi = \phi_0$ and $\phi = \phi_0 + 2\pi$. Substituting Eq. (33) into the rotation matrix (Eq. (30)) gives the following expression for the adiabatic states:

$$\psi_1 = \cos\left[\frac{\phi_0}{2}\right]\varphi_A - \sin\left[\frac{\phi_0}{2}\right]\varphi_B \quad (34)$$

and

$$\psi_2 = \sin\left[\frac{\phi_0}{2}\right]\varphi_A + \cos\left[\frac{\phi_0}{2}\right]\varphi_B \quad (35)$$

Next, we substitute $\phi = \phi_0 + 2\pi$ to show that the adiabatic wave function has indeed changed sign after the 360° rotation:

$$\begin{aligned}\psi_1 &= \cos\left[\frac{\phi_0 + 2\pi}{2}\right]\varphi_A \\ &\quad - \sin\left[\frac{\phi_0 + 2\pi}{2}\right]\varphi_B \\ &= \sin\left[\frac{\phi_0}{2}\right]\varphi_A - \cos\left[\frac{\phi_0}{2}\right]\varphi_B \\ &= -\psi_1 \end{aligned} \quad (36)$$

Because single-valuedness of the wave function is one of the basic postulates of quantum mechanics, this result implies that the conical intersection is a singularity. This singularity is a consequence of the separation between electronic and nuclear degrees of freedom, which is not valid near surface crossings. Thus, the singularity only exists for the adiabatic electronic wave function and is remedied by the nuclear wave function, so that the total molecular wave function is single-valued function. Furthermore, as illustrated schematically in Figure 3.4, rotation by 90° permutes the order of the electronic states, as is demonstrated by substituting $\theta + \pi$ into Eq. (33):

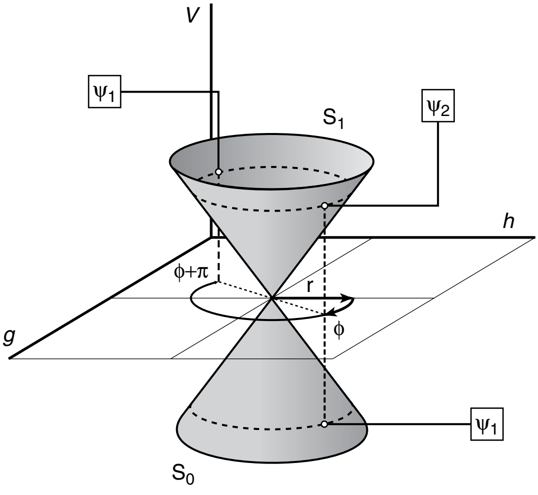

Fig. 3.4 In the branching space (x,y), points lying on a circle with a small radius r and centered at the apex of the double cone are *diabatically* related. If we select a point on one of the surfaces and move it to the opposite side of the circle ($\phi \to \phi + \pi$), its wave function becomes equal to the wave function of the other surface at the original position. If we complete the circle, the point is back at its original position, but its wave function has changed sign (not shown, see text).

$$\begin{aligned}\psi_1 &= \cos\left[\frac{\phi_0+\pi}{2}\right]\varphi_A \\ &\quad - \sin\left[\frac{\phi_0+\pi}{2}\right]\varphi_B \\ &= \sin\left[\frac{\phi_0}{2}\right]\varphi_A \\ &\quad - \cos\left[\frac{\phi_0}{2}\right]\varphi_B = -\psi_2 \qquad (37)\end{aligned}$$

As we will show in Section 3.2.3, this characteristic of the conical intersection can be used to detect when the seam is crossed in a classical molecular dynamics simulation of a photochemical reaction.

As we will discuss in the applications section, the conical intersection seam is the central mechanistic feature in a photochemical reaction. The conical intersection provides a funnel for efficient radiationless decay between electronic states (Figure 3.2). To illustrate the relationship between the surface crossing and photochemical reactivity, we can draw a parallel with the transition state in ground state chemistry. The transition state forms the bottleneck through which the reaction must pass on its way from reactants to products. A transition state separates the reactant and product energy minima along the reaction path. A conical intersection also forms a bottleneck that separates the excited state branch of the reaction path from the ground state branch. The crucial difference between conical intersections and transition states is that, although the transition state must connect the reactant minimum to a single product minimum via a single reaction path, an intersection is a spike on the ground state energy surface and thus connects the excited state reactant to two or more products on the ground state via several reaction paths.

3.2.3
Excited State Molecular Dynamics

To model the dynamics of a photochemical reaction, the ground- and excited state potential energy surfaces must be described accurately. As illustrated in Figure 3.1, the reaction starts in the excited state (S_1), but ends in the ground state (S_0). Therefore it is essential to model the radiationless transition between the excited and ground state surfaces in a manner that is consistent with a QM treatment.

If a sufficiently accurate description of the adiabatic Born–Oppenheimer potential energy surfaces is available, nuclear dynamics can be computed by numerically integrating either the time-dependent Schrödinger equation (Eq. (3)), or Newton's equations of motion. In the first case, quantum mechanics is used to follow the dynamics of nuclear wave packets ($\chi_j(\mathbf{R})$, Eq. (9)), evolving on electronic potential energy surfaces. Within this approach transitions between surfaces near or at conical intersections can be described correctly. A wave packet traveling through or near an intersection spawns new packets on both surfaces. The transfer probability is controlled by the nonadiabatic coupling elements. At the conical intersection, the coupling has its maximal strength, resulting in an efficient transfer of the complete wave packet to the lower surface.

A requirement for wave packet dynamics is that the relevant potential energy surfaces have been computed beforehand. As the computational costs associated with precomputing these surfaces increases rapidly with the number of coordinates in the system, wave packet dynamics is restricted to small isolated molecules. Alternatively, the multidimensional configuration space can be reduced to a lower dimensional subspace in which quantum dynamics is feasible (Burghardt, 2001). However, choosing suitable coordinates is not straightforward and requires averaging over the remaining degrees of freedom. Furthermore, the choice of the coordinates can strongly bias the outcome of a simulation. Therefore, for photobiological problems, the size and complexity of the systems involved severely limit the applicability of wave packet simulations.

Alternatively, Newton's equations of motion can be used to compute molecular dynamics trajectories. The underlying assumption in this case is to ignore the QM character of the nuclei. The nuclei are thus assumed to be classical particles moving on a single adiabatic potential energy surface. In terms of computational effort, classical molecular dynamics is orders of magnitude more efficient than wave packet dynamics, and is therefore routinely used for computing the time evolution of large biomolecular systems. Classical mechanics has the additional advantage that the potential energy surface can be computed on the fly. Forces are evaluated for the geometry at timestep t and used to compute the geometry at the next time step $t + \Delta t$. Thus, only at the configurations sampled by the classical trajectory, electronic structure calculations are required. For high-dimensional systems, for which computing potential energy surfaces beforehand is no longer possible, the on-the-fly strategy is the only way to perform a molecular dynamics simulation.

Classical mechanics provides a computationally cheap alternative to wave packet dynamics. However, because quantum effects are ignored, population transfer cannot occur and classical trajectories are restricted to a single potential energy surface. Therefore, in contrast to wave packet dynamics, radiationless transitions do not take place spontaneously. Instead, a binary decision to jump to a different electronic surface must be made at every timestep in a single trajectory. The criterion for switching between electronic states must result in a distribution of state populations over many trajectories that reflects the populations of a full quantum mechanical treatment. Furthermore, in contrast to wave packet dynamics, classical trajectories do not capture coherence effects. When a nuclear wave packet originally traveling on a single adiabatic potential energy surface encounters a crossing, it typically produces two subpackets, or offsprings, one on each surface (Thachuk, Ivanov and Wardlaw, 1998). After such spawning event, the new wave packets will still interfere with each other. However, as these subpackets travel on different surfaces and often have different initial velocities on their respective surfaces, they are well separated in phase space and it is highly unlikely that they will encounter each other again, especially in high-dimensional systems, such as solvated biomolecules. Therefore, the spawned wave packets are effectively incoherent (Thachuk, Ivanov and Wardlaw, 1998; Onuchic and Wolynes, 1998), and the classical trajectory approximation is justified in most situations.

3.2.3.1 **Surface Hopping**

The interest in understanding photochemical processes has prompted the development of methods for the treatment of nonadiabatic effects in classical molecular dynamics. Most, if not all of these methods are based on surface hopping: nuclei move on a single potential energy surface and nonadiabatic transitions are included by allowing the trajectory to hop from one surface to another. The size and complexity of biomolecular systems necessitates the use of computationally cheap surface-hopping algorithms. In this section we review two of the most widely used hopping procedures for excited state dynamics in biomolecules, diabatic hopping and Tully's fewest-switches surface hopping.

As formulated independently by Landau and Zener, in one dimension the probability of a transition between two electronic states, ψ_2 and ψ_1, is given by

$$P_{2\to 1} = \exp\left[-\frac{1}{4}\pi\xi\right] \tag{38}$$

The Massey parameter ξ is defined as (Desouter-Lecomte and Lorquet, 1979)

$$\xi = \frac{\Delta E}{\hbar\frac{\partial \mathbf{Q}}{\partial t}\cdot \mathbf{g}(\mathbf{Q})} \tag{39}$$

with $\mathbf{Q}$ representing a one-dimensional nuclear reaction coordinate, ΔE the energy gap between the adiabatic states, and

$$\mathbf{g}(\mathbf{Q}) = \langle\psi_1|\nabla_{\mathbf{Q}}\psi_2\rangle \tag{40}$$

After differentiation of ψ_2 with respect to t (via $\frac{\partial}{\partial t}\mathbf{Q}$), ξ can be rewritten as

$$\xi = \frac{\Delta E}{\hbar\left\langle\psi_1|\frac{\partial\psi_2}{\partial t}\right\rangle} \tag{41}$$

To decide when to undergo a transition to a different potential energy surface, $\langle\psi_1|\frac{\partial}{\partial t}\psi_2\rangle$ needs to be computed at every timestep of the simulation. For a small timestep Δt to integrate the classical equations of motion for the nuclei, we have at t:

$$\begin{aligned}\psi_1(t) &= \varphi_A\\ \psi_2(t) &= \varphi_B\end{aligned} \tag{42}$$

where the $\varphi_{A,B}$ are the diabatic electronic states. At $t+\Delta t$, the states will have become mixed due to the nonadiabatic coupling. In the limit of an infinitesimally small timestep, the change in the wave functions becomes

$$\begin{aligned}\psi_1(t+\Delta t) &= \varphi_A + \beta\varphi_B\\ \psi_2(t+\Delta t) &= -\beta\varphi_A + \varphi_B\end{aligned} \tag{43}$$

with β being a mixing coefficient. Numerical differentiation (finite differences) of the wave function gives

$$\frac{\partial}{\partial t}\psi_2 = -\beta\frac{\varphi_A}{\Delta t} \tag{44}$$

and yields the following expression:

$$\left\langle\psi_1|\frac{\partial}{\partial t}\psi_2\right\rangle \approx -\frac{\beta}{\Delta t} \tag{45}$$

Since

$$\langle\psi_1(t)|\psi_2(t+\Delta t)\rangle = -\beta \tag{46}$$

we can compute $\langle\psi_1(t)|\psi_2(t+\Delta t)\rangle$ as a numerical approximation for $\langle\psi_1|\frac{\partial}{\partial t}\psi_2\rangle$ in the Massey parameter (Eq. (41)).

With the energy gap ΔE and $\langle\psi_1(t)|\psi_2(t+\Delta t)\rangle$, we can use the Landau–Zener formula (Eq. (38)) to calculate at every timestep the probability of a transition to the other surface. In principle, the transition probabilities could be used to spawn off multiple trajectories. However, such spawning procedure leads to an enormous increase of computational effort. Instead, hops are usually restricted to situations where the transition probability approaches unity. This happens at the conical intersection seam, where $\Delta E \approx 0$ and $\| \langle \psi_1(t)|\psi_2(t+\Delta t)\rangle \| \approx 1$. The former is trivially true by the definition of an intersection, and the latter follows from Eq. (37): As shown in Figure 3.4, passing through the intersection during a single timestep (Δt) leads to geometries at t and $t+\Delta t$ that are opposite to each other with respect to the apex in the branching space. Therefore, crossing the seam is equivalent to rotating the wave function by half a circle (Figure 3.4):

$$\begin{aligned}
&\langle \psi_1(t)|\psi_2(t+\Delta t)\rangle \\
&\quad = \langle \psi_1(\phi)|\psi_2(\phi+\pi)\rangle \\
&\quad = -\langle \psi_1(\phi)|\psi_1(\phi)\rangle \\
&\quad = -\langle \psi_1(t)|\psi_1(t)\rangle \\
&\quad = -1
\end{aligned} \tag{47}$$

If hopping is allowed only at the conical intersection seam, a classical trajectory never leaves the diabatic surface, and energy and momentum are obviously conserved. In principle, this strict diabatic hopping criterium could lead to an underestimation of the population transfer probability, because a surface hop in regions with strong nonadiabatic coupling far from the intersection is prohibited. However, because of the high dimensionality of the seam, most trajectories can usually encounter such regions of high transfer probability. The Landau–Zener model is clearly an approximation, but helps one to keep a proper physical insight, which is crucial in understanding complex systems.

Tully and coworkers have proposed an alternative hopping scheme in which switches between adiabatic states are described by a stochastic process (Tully and Preston, 1972; Tully, 1990, 1991). The stochastic nature of the hops implies that only the average over many trajectories can be compared to observable quantities. At each timestep of the simulation, there is a probability that a trajectory propagating on one potential energy surface will hop to another surface. The hopping probability is derived from a *primary* electronic wave function $\Psi^e(t, \mathbf{r}, \mathbf{R})$. This wave function is expanded on the basis of the adiabatic states $\psi_j(\mathbf{r};\mathbf{R})$:

$$\Psi^e(t) = \sum_j c_j(t)\psi_j \tag{48}$$

where $c_i(t)$ are time-dependent expansion coefficients. Substituting the primary wave function into the time-dependent Schrödinger equation (Eq. (3)), multiplication on the left by $\psi_k(\mathbf{r};\mathbf{R})$ and integration over r yields

$$i\hbar\frac{\partial c_k(t)}{\partial t} = \sum_j c_j(t)\left\{H^e_{kj}(\mathbf{R}) - i\hbar\dot{\mathbf{R}}\cdot\mathbf{d}_{kj}\right\} \tag{49}$$

where the matrix elements are defined as

$$H^e_{kj}(\mathbf{R}) = \langle \psi_k(\mathbf{r};\mathbf{R})|H^e(\mathbf{R})|\psi_j(\mathbf{r};\mathbf{R})\rangle \tag{50}$$

The nonadiabatic coupling vectors

$$\mathbf{d}_{kj} = \langle \psi_k(\mathbf{r};\mathbf{R})|\nabla_{\mathbf{R}}\psi_j(\mathbf{r};\mathbf{R})\rangle \tag{51}$$

are obtained by applying the chain rule:

$$\begin{aligned}
&\langle \psi_k(\mathbf{r};\mathbf{R})|\frac{\partial}{\partial t}\psi_j(\mathbf{r};\mathbf{R})\rangle \\
&\quad = \langle \psi_k(\mathbf{r};\mathbf{R})|\nabla_{\mathbf{R}}\psi_j(\mathbf{r};\mathbf{R})\rangle\cdot\dot{\mathbf{R}}
\end{aligned} \tag{52}$$

Because the Hamiltonian H^e_{jk} is, by definition, diagonal in the adiabatic representation, population can only be transferred between the adiabatic states $\psi_j(\mathbf{r};\mathbf{R})$ and $\psi_k(\mathbf{r};\mathbf{R})$ by the nonadiabatic coupling between nuclei and electrons ($\dot{\mathbf{R}} \cdot \mathbf{d}_{kj}$).

For what follows, it is convenient to rewrite Eq. (49) in the equivalent density matrix notation. The elements of the density matrix $\boldsymbol{\rho}(t)$ are defined as

$$\rho_{kj}(t) = c_k(t)c_j^*(t) \tag{53}$$

In this notation Eq. (49) becomes

$$\begin{aligned} \mathrm{i}\hbar\dot{\rho}_{kj}(t) = \sum_l \rho_{lj}(t) \left[H^e_{kl} - \mathrm{i}\hbar\dot{\mathbf{R}} \cdot \mathbf{d}_{kl}\right] \\ - \rho_{kl}(t) \left[H^e_{lj} - \mathrm{i}\hbar\dot{\mathbf{R}} \cdot \mathbf{d}_{lj}\right] \end{aligned} \tag{54}$$

where we used the following properties on an orthonormal basis:

$$\mathbf{d}^*_{lj} = -\mathbf{d}_{jl} \tag{55}$$

and

$$\mathbf{d}_{jj} = 0 \tag{56}$$

The diagonal elements ρ_{jj} are the electronic state populations, and the off-diagonal elements ρ_{jk} describe coherence.

In Tully's approach, there is a distinction between the primary electronic wave function $\Psi^e(t)$ and the auxiliary adiabatic wave function ψ_n. The primary wave function defines all quantum observables, such as the populations of the adiabatic states, and is propagated in time along with the classical nuclear trajectory. The auxiliary adiabatic wave function defines the potential energy surface on which the nuclear trajectory evolves and is not propagated in time, but can make stochastic switches to other adiabatic states.

In order to maintain the correct quantum statistical distribution of states in an ensemble of surface-hopping trajectories, the probabilities of switching between different adiabatic states must reflect the populations of those adiabatic states in the primary electronic wave function. These populations or occupation probabilities are the diagonal elements of the density matrix $\boldsymbol{\rho}(t)$ (Eq. (53)). The rate at which the populations change along a nuclear trajectory is given by

$$\dot{\rho}_{kk} = \sum_{l \neq k} b_{kl} \tag{57}$$

where, from Eq. (54),

$$b_{kl} = 2\hbar^{-1}\mathrm{Im}\left[\rho^*_{kl}H^*_{kl}\right] - 2\mathrm{Re}\left[\rho^*_{kl}\dot{\mathbf{R}} \cdot \mathbf{d}_{kl}\right] \tag{58}$$

Since adiabatic basis states are used in the expansion of the primary electronic wave function $\Psi(t)$, the imaginary term in this expression is always zero.

During a very small time interval δt, the change in the population of state ψ_k is approximately $\dot{\rho}_{kk}\delta t$. If this state is only coupled to one other state, for example ψ_j, the change in population of state ψ_k is $\delta\rho_{kk} \approx \dot{\rho}_{kk}\delta t = b_{kj}\delta t$. Since no electrons are created or destroyed, the change in the population of state ψ_j, due to its coupling with ψ_k is $\delta\rho_{jj} = -\delta\rho_{kk} \approx -b_{kj}\delta t$. In what follows we assume that $b_{kj} > 0$, that is, the population of ψ_k increases due to the coupling, whereas that of ψ_j decreases. To maintain the correct quantum statistical distribution of adiabatic states in an ensemble of N_{ens} trajectories, the number of switches from ψ_j to ψ_k in the time interval δt must exceed the number of switches from ψ_k to ψ_j by $N_{\mathrm{ens}}b_{kj}\delta t$. Tully argued that in a simulation the total number of switches should be minimal (Tully, 1990). A minimum number of state switches is realized if $N_{\mathrm{ens}}b_{kj}\delta t$ switches from ψ_j to ψ_k occur, and none from ψ_k

to ψ_j. Since there are initially $N_{\text{ens}}\rho_{jj}$ trajectories in state ψ_j, the probability that one of these will switch to ψ_k during the time interval δt is

$$g_{jk} = \frac{N_{\text{ens}} b_{kj} \delta t}{N_{\text{ens}} \rho_{jj}} = \frac{b_{kj}}{\rho_{jj}} \delta t \tag{59}$$

and the probability of a switch from ψ_k to ψ_j should be zero. Therefore the fewest-switches algorithm computes the transition probabilities as

$$g_{jk} = \max\left[0, \frac{b_{kj}\Delta t}{\rho_{jj}}\right] \tag{60}$$

where Δt is the integration time step in a simulation. Being based on the rates of change of the populations, the fewest-switches algorithm ensures that surface hops only occur if the trajectory is in regions where the nonadiabatic coupling vectors $\mathbf{d}_{jk}$ are nonzero. Outside those regions, the nonadiabatic coupling vectors are negligible and the adiabatic state populations no longer change, that is, $\dot{\rho}_{kk} = 0$.

In order to conserve energy, the velocities of the nuclei are adjusted, whenever a state switch is made to an adiabatic state that has a different energy at the current nuclear configuration. Since nuclei can only induce transitions between electronic states if their velocity vectors overlap with the nonadiabatic coupling vectors ($\dot{\mathbf{R}} \cdot \mathbf{d}_{kj}$), Tully proposed to adjust the components of the nuclear velocities parallel to these coupling vectors (Tully, 1990). Thus the velocities of the nuclei are adjusted, as if the nuclei were subjected to a force in the direction of the nonadiabatic coupling vector, and the work done by that force was used to promote the system to another adiabatic state.

In a surface-hopping simulation, the new velocity of each nucleus $\dot{\mathbf{R}}^{i,\text{new}}$, after a state switch from ψ_k to ψ_j, is calculated as Fang and Hammes-Schiffer, 1999)

$$\dot{\mathbf{R}}^{i,\text{new}} = \dot{\mathbf{R}}^i - \frac{1}{M^i}\gamma_{kj}\mathbf{d}_{kj} \tag{61}$$

where M^i is the mass of nucleus i and $\mathbf{d}_{kj}$ the nonadiabatic coupling vector (Eq. (51)). The scaling factor γ_{kj} is defined as

$$\gamma_{kj} = \begin{cases} \dfrac{\beta_{kj} + \sqrt{\beta_{kj}^2 + 4\alpha_{kj}\left[V_k(\mathbf{R}) - V_j(\mathbf{R})\right]}}{2\alpha_{kj}} \\ \text{for} \quad \beta_{kj} < 0 \\ \dfrac{\beta_{kj} - \sqrt{\beta_{kj}^2 + 4\alpha_{kj}\left[V_k(\mathbf{R}) - V_j(\mathbf{R})\right]}}{2\alpha_{kj}} \\ \text{for} \quad \beta_{kj} \geq 0 \end{cases} \tag{62}$$

where $V_n(\mathbf{R})$ is the potential energy of state ψ_n at the current nuclear configuration, and we have introduced

$$\alpha_{kj} = \frac{1}{2M^i}\left|\mathbf{d}_{kj}\right|^2 \tag{63}$$

and

$$\beta_{kj} = \dot{\mathbf{R}}^i \cdot \mathbf{d}_{kj} \tag{64}$$

If there is not enough velocity (kinetic energy) in the direction of the nonadiabatic coupling vector to maintain energy conservation during a hop, the hop is classically forbidden. There are two generally accepted approaches for dealing with classically forbidden state switches. In the first approach, the hops are rejected, and the velocities parallel to the nonadiabatic coupling vector are reversed. If the system attempts to make the hop when there is not sufficient energy, it falls back as if it has encountered a too high barrier. In the other approach, the switch is also rejected, but now the velocities are not changed. The rationale for the second approach is that, if there is not enough energy for making a hop, nothing will happen and the system remains in the current state (Müller and Stock, 1997). Classically forbidden hops lead to discrepancies between the QM occupation probabilities of the adiabatic states and the fraction of trajectories found in those adiabatic states in the ensemble (Fang and Hammes-Schiffer, 1999).

Another source of error is the coherent propagation of the primary electronic wave function (Fang and Hammes-Schiffer, 1999; Thachuk, Ivanov and Wardlaw, 1998), which can lead to inconsistencies between quantum probabilities and ensemble averages. When a trajectory initially moving on state i passes a region of nonadiabatic coupling, the other adiabatic states become populated and the primary electronic wave function no longer exists as a single adiabatic state, but as a mixture of different states. After leaving the nonadiabatic region, the primary electronic wave function remains a superposition of adiabatic states, and is propagated along the trajectory as a mixed state in the rest of the simulation. This essentially means that, together with the real trajectory in state i, a number of virtual trajectories are evolved (Thachuk, Ivanov and Wardlaw, 1998). These virtual trajectories evolve on the adiabatic surfaces associated with the other adiabatic states that are populated in the primary wave function. Although they are on different surfaces, the virtual trajectories travel at the same velocity and in the same direction as the real trajectory and can interfere with it. As a consequence, coherence between the electronic wave functions of these virtual trajectories and the real trajectory is maintained. At a second passage through a region of nonadiabatic coupling, the interference of virtual trajectories with the real one influences the transition probabilities.

In reality, a wave packet quickly looses coherence with the wave packets on the other electronic surfaces after leaving a crossing region and will not interfere with the other wave packets when it encounters a next crossing (Thachuk, Ivanov and Wardlaw, 1998; Onuchic and Wolynes, 1998). This coherence loss is attributed to the rapid divergence in phase space of wave packets on different electronic surfaces. In an exact QM calculation of the system, a fully coherent propagation of the electronic wave function will not cause problems, since the nuclear wave functions quickly destroy any coherence between wave packets on different adiabatic surfaces. In surface hopping, on the other hand, nuclear wave functions are replaced by classical trajectories. Since a classical trajectory has no wave character, it can not exist on different adiabatic surfaces simultaneously. Propagating the primary electronic wave function along a single trajectory therefore introduces artificial coherence between this trajectory and virtual trajectories on other surfaces.

An *ad hoc* solution to the coherence problem in surface hopping is to reset the primary electronic wave function $\Psi^e(t)$ to the currently occupied auxiliary adiabatic state ψ_n (i.e. $c_j(t) = \delta_{jn}$) each time a trajectory leaves a hopping region (Fang and Hammes-Schiffer, 1999). The resetting introduces artificial decoherence in the coherent propagation of the primary electronic wave function, and thus washes out any interference with virtual trajectories. As a result, the ensemble averages are in agreement with the quantum mechanical probabilities.

In contrast to the diabatic hopping approach, hops are not restricted to occur at the conical intersection seam, but can occur wherever the nonadiabatic coupling is strong enough, even at nonzero energy gaps. In principle, population transfer is not underestimated by this method. Energy conservation, however, which is fulfilled in the diabatic hopping approach, is more difficult, and an *ad hoc* scaling of nuclear velocities is introduced. In terms of computational effort, the fewest-switches approach is more demanding as it requires calculation of the nonadiabatic coupling vector. Following Yarkony and coworkers, this vector can be related to the interstate coupling vector (Lengsfield, Saxe and Yarkony, 1984; Lengsfield and Yarkony, 1992)

$$\mathbf{h}_{ij}(\mathbf{R}) = \mathbf{C}_i^{\dagger} \frac{\partial \mathbf{H}}{\partial \mathbf{R}} \mathbf{C}_j \tag{65}$$

where $\mathbf{C}_i$ are the configuration interaction coefficients and $\mathbf{H}$ is the configuration interaction Hamiltonian matrix. With the interstate coupling, the nonadiabatic coupling vector can be computed as

$$\mathbf{d}_{ij}(\mathbf{R}) = \frac{\mathbf{h}_{ij}(\mathbf{R})}{V_i - V_j} + \sum_{a,b} \left(\Gamma_{ij}\right)_{ab} \left\langle \Phi_a \right| \frac{\partial \Phi_b}{\partial \mathbf{R}} \right\rangle \tag{66}$$

where Γ_{ij} is the one-electron transition density matrix and Φ denotes molecular orbitals. The computational cost associated with evaluating these gradients increases steeply with the number of nuclear degrees of freedom. These costly computations are avoided in the diabatic hopping method. Both approaches can yield mechanistic insights and, in the limit of a sufficiently high number of trajectories, can be used to estimate observable quantities, such as excited state lifetimes, and quantum yields.

3.2.3.2 **Excited State Quantum Chemistry**

In this subsection, we will highlight the challenges associated with excited state electronic structure calculations that are required for on-the-fly molecular dynamics simulations of photochemical reactions. A number of theoretical methods for the treatment of excited electronic states have been developed. Although highly accurate methods have become available over the past years, they are usually too time consuming for systems larger than a few atoms. Therefore, most of these methods are not yet applicable for molecular dynamics simulations of large biomolecular systems. Alternatively, simple force fields or existing *semiempirical* methods that are computationally efficient may be used, but their applicability is limited, unless properly reparameterized (Warshel, 1976; Toniolo *et al.*, 2004). Therefore, for on-the-fly molecular dynamics, a compromise between cost and accuracy has to be made.

A computationally feasible approach to describe excited state electronic structure is the equation of motion coupled cluster (EOM-CCSD) method and *ab initio* dynamics simulations of small isolated molecules have been performed at the EOM-CCSD level (Baeck and Martinez, 2003). However, EOM-CCSD can only work well if the underlying CCSD method provides a good description of the ground electronic state. This can cause problems when bonds are being broken or formed and the ground electronic state has a significant multiconfigurational character. The description of electronic states with a strong double excitation character also causes problems (Bartlett and Musial, 2007).

Time-dependent density functional theory (TD-DFT) offers a computationally very efficient approach to describe excited states and consequently has been used in excited state molecular dynamics simulations (Tavernelli, Rohrig and Rothlisberger, 2005). Similar to EOM-CCSD, TD-DFT suffers from the deficiencies of the underlying monoconfigurational DFT description of the ground state in regions of bond breaking and bond formation. Moreover, TD-DFT is known to encounter severe problems in describing valence states of molecules exhibiting extended π-systems, doubly excited states, and charge transfer excited states (Dreuw and Head-Gordeon, 2005).

The problems associated with methods that are based on a single reference configuration, such as EOM-CCSD and TD-DFT, demonstrate that for computing excited states, multiconfigurational methods are required to provide wave functions that are sufficiently flexible to describe bond rearrangements, electronic state mixing, and electronic reorganizations. In addition, to calculate molecular dynamics trajectories analytical energy gradients are necessary. Since the complete active-space self-consistent field (CASSCF) method fulfills these requirements, it has often been used in the framework of excited state dynamics simulations (Coe and Martinez, 2006, 2005; Weingart *et al.*, 2004; Boggio-Pasqua *et al.*, 2002; Sanchez-Galvez *et al.*, 2000). In CASSCF, a judicious set of occupied and virtual orbitals is chosen, the so-called active-space orbitals. In this active space, a full configuration interaction calculation is performed, while the other orbitals are kept doubly occupied or empty in all configurations. The active orbitals are optimized such that the electronic energy of the state considered is minimal. Alternatively, the average energy of the states under study is minimized (state-averaged approach), if state bias or root-flipping problems (Werner and Meyer, 1981) that occur near surface crossing regions (Worth and Robb, 2002), have to be avoided.

The CASSCF method captures to a large extent the so-called *static* electron correlation. However, owing to the necessary truncation of the active space, it does not recover *dynamic* electron correlation completely. Dynamic correlation is known to play a key role in the quantitative description of barrier heights and excitation energies. Thus, a higher-level treatment that includes dynamic electron correlation effects is desirable. Unfortunately, methods that resolve both static and dynamic correlations tend to be computationally too demanding and furthermore often lack the required analytical energy gradients. Because in most cases CASSCF describes the topology of the potential energy surfaces of the involved states sufficiently accurate, it is widely used for mechanistic studies of photochemical reactions (Lipkowitz and Boyd, 2000).

Dynamic correlation is accounted for in multireference perturbation theory approaches, such as Complete Active Space Perturbation Theory to Second Order (CASPT2) (Roos, 1999). CASPT2 provides a means to include dynamics correlation, while simultaneously describing static correlation. Recently, analytical CASPT2 energy gradients (Celani and Werner, 2003) have become available, which have opened the way for molecular dynamics simulations. Coe *et al.* have already used these gradients to perform an *ab initio* MD simulation on the excited state proton transfer reaction in methyl salicylate (Coe, Levine and Martinez, 2007). However, the computational cost of this method still prevents its use for larger biomolecular systems, in which the number of correlated electrons is too large.

Alternatively, dynamic electron correlation is included to some extent in the restricted active-space self-consistent field (RASSCF) method (Roos, 1999). RASSCF allows larger active spaces and thus provides more flexibility in the choice of the active orbitals than CASSCF (Boggio-Pasqua *et al.*, 2004). The larger active space is subdivided into three classes: orbitals with a limited number of valences, a fully active orbital set, and orbitals with a limited number of electrons. In addition to including dynamic electron correlation, RASSCF can be used as an approximation to CASSCF. By eliminating the unimportant configurations, the size of the configuration interaction problem can be greatly reduced in RASSCF compared to CASSCF without compromising accuracy. Because analytical gradients are available, the RASSCF method can be expected to be used in excited state dynamics simulations in the future. Unfortunately, however, it remains a difficult task even in RASSCF to select the correct orbital set for a given photochemical problem.

A promising alternative that circumvents the choice of active orbitals lies in the use of semiempirical configuration interaction methods. These methods offer a lower cost alternative, while still taking into account the correlation effects necessary to describe excited states. For example, the recently developed semiempirical OM2 method has been shown to describe accurately the well-known conical intersections of small molecules (Keal, Koslowski and Thiel, 2007). Thus, the use of new semiempirical methods, such as OM2, could hold great promise for nonadiabatic molecular dynamics simulations of very large molecular systems in the near future.

3.2.3.3 Mixed Quantum Classical Molecular Dynamics

MD computer simulations of biological systems have come of age. Since the first application of MD on a small protein in vacuum more than three decades ago (McCammon *et al.*, 1976), advances in computer power, algorithmic developments, and improvements in the accuracy of the used interaction functions have established MD as an important and predictive technique to study dynamic processes at atomic resolution (Berendsen, 2001). In the interaction functions, the so-called MM force field, simple chemical concepts are used to describe the potential energy of the system (Jensen, 2001):

$$
\begin{aligned}
V_{\mathrm{MM}} = & \sum_{i}^{N_{\mathrm{bonds}}} V_i^{\mathrm{bond}} + \sum_{j}^{N_{\mathrm{angles}}} V_j^{\mathrm{angle}} \\
& + \sum_{l}^{N_{\mathrm{torsions}}} V_l^{\mathrm{torsion}} \sum_{i}^{N_{\mathrm{MM}}} \sum_{j>i}^{N_{\mathrm{MM}}} V_{ij}^{\mathrm{Coul}} \\
& + \sum_{i}^{N_{\mathrm{MM}}} \sum_{j>i}^{N_{\mathrm{MM}}} V_{ij}^{\mathrm{LJ}} \qquad (67)
\end{aligned}
$$

where N_{MM} is the number of atoms in the system. Bonds and angles (V^{bond}, V^{angle}) are normally modeled by harmonic functions, and torsions by periodic functions (V^{torsion}). The pairwise electrostatic interaction between atoms with a partial charge (Q_i) is given by Coulomb's law:

$$V_{ij}^{\mathrm{Coul}} = \frac{e^2 Q_i Q_j}{4\pi\varepsilon_0 R_{ij}} \qquad (68)$$

where R_{ij} denotes the interatomic distance, e the unit charge, and ε_0 the dielectric constant. Short-range Pauli repulsion and long-range dispersion attraction are most often described by a single Lennard-Jones potential:

$$V_{ij}^{\text{LJ}} = \left(\frac{C_{12}^{ij}}{R_{ij}}\right)^{12} - \left(\frac{C_6^{ij}}{R_{ij}}\right)^{6} \qquad (69)$$

with C_{12}^{ij} and C_6^{ij} the repulsion and attraction parameters, respectively, which depend on the atom types involved.

Electrons are thus ignored completely in molecular mechanics force fields. Their influence is expressed by empirical parameters that are valid for the ground state of a given covalent structure. Therefore, processes that involve electronic rearrangements, such as photochemical reactions, cannot be described at the MM level. Instead, these processes require a quantum mechanics description. As we have discussed above, the computational effort associated with computing excited state electronic structure puts severe constraints on the size of the system that can be studied. To overcome this limitation for biological systems, which are typically orders of magnitude too large for a complete quantum chemical treatment, methods have been developed that treat a small part of the system at an appropriate QM level, while retaining the computationally cheaper force field (MM) for the remainder. This hybrid QM/MM strategy was originally introduced by Warshel and Levitt (1976) and is illustrated in Figure 3.5.

The justification for dividing a system into regions, which are described at different levels of theory, is the local character of chemical reactions in condensed phases. A distinction can usually be made between a "reaction center" with atoms that are directly involved in the reaction and a "spectator" region, in which the atoms do not directly participate in the reaction. For example, most reactions in solution involve the reactants and the first few solvation shells. The bulk solvent is hardly affected by the reaction, but can influence the reaction via long-range interactions. The same is true for most enzymes, in which the catalytic process is restricted to an active site. The rest of the protein provides an electrostatic background that can facilitate the reaction.

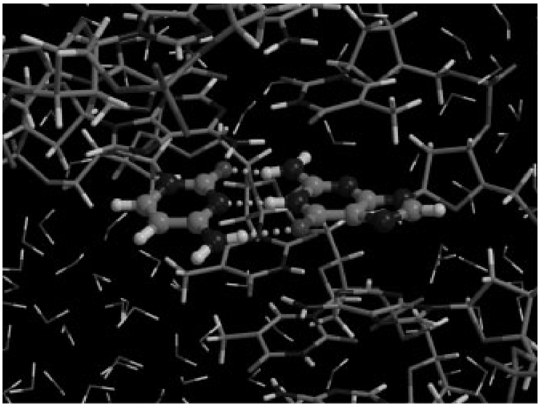

Fig. 3.5 The QM/MM partitioning scheme used in recent simulations of excited state proton transfer in a Watson–Crick Cytosine–Guanine base pair in DNA. The atoms of the QM subsystem are shown in ball-and-stick representation and MM atoms are shown as thin sticks. The CASSCF method was employed to model the electronic structure, while the Amber (Wang, Cieplak and Kollman, 2000) force field was used for the rest of the system.

The hybrid QM/MM Hamiltonian contains three classes of interactions: between atoms in the QM region, between atoms in the MM region, and between atoms in the QM and MM region

$$H^{\text{hybrid}} = H_{\text{QM}} + H_{\text{MM}} + H_{\text{QM/MM}} \tag{70}$$

The interactions within the QM and MM regions are relatively straightforward to describe, that is, at the QM and MM levels, respectively. The interaction between the two subsystems is more difficult to describe and several approaches have been proposed.

In the most simple approach, the QM subsystem is mechanically embedded in the MM system and kept in place by force field interactions, that is, bonds, angles, torsions and Lennard-Jones. With the exception of these interactions, the two systems are treated independently. Thus a quantum chemistry calculation is performed on an isolated QM subsystem, while a force field calculation is performed on the MM region. An improvement of the model is to use the isolated electronic wave function to derive partial atomic charges for the QM atoms and use these charges to compute the electrostatic QM/MM interactions with the MM atoms.

In the more popular electronic embedding scheme of Field and coworkers (Field, Bash and Karplus, 1990), the MM atoms enter the electronic Hamiltonian, as if they were QM nuclei:

$$\begin{aligned} H^{e}_{\text{QM/MM}} &= H^{e} + \sum_{i}^{n_e}\sum_{K}^{N_{\text{MM}}} \frac{Q_i}{4\pi\varepsilon_0 r_{iK}} \\ &= -\frac{\hbar^2}{2m_e}\sum_{i}^{n_e}\nabla_i^2 + \sum_{i}^{n_e}\sum_{j>i}^{n_e}\frac{e^2}{4\pi\varepsilon_0 r_{ij}} \\ &\quad - \sum_{i}^{n_e}\sum_{A}^{N_{\text{QM}}}\frac{e^2 Z_A}{4\pi\varepsilon_0 r_{iA}} + \sum_{i}^{n_e}\sum_{K}^{N_{\text{MM}}}\frac{e^2 Q_K}{4\pi\varepsilon_0 r_{iK}} \end{aligned} \tag{71}$$

where H^e is the original electronic Hamiltonian for the isolated QM system, defined in Eq. (5); n_e is the number of electrons, N_{QM} the number of QM nuclei, and N_{MM} the number of MM atoms; Z_A and Q_K are the nuclear and partial charges of QM nucleus A and MM atom K, respectively; and m_e denotes the electron mass. Because the MM atoms enter the Hamiltonian, the electronic wave function is polarized by the environment. Simultaneously, the electrons are exerting electrostatic forces on both QM nuclei and MM atoms. Problems may arise if the MM atoms near the QM region have high partial charges. In this case, the electrons are strongly attracted by such MM atoms, and the wave function can become overpolarized. Penetration of electron density in to the MM region is an artefact of ignoring the electrons of the MM atoms. A remedy for this spill-out effect is to use gaussian-shaped charge densities rather than point charges to represent partially charged MM atoms (Amara and Field, 2003).

Interactions between the nuclei in the QM region, and between QM nuclei and MM atoms are described by Coulomb's law:

$$\begin{aligned} H^{\text{nuc}}_{\text{QM/MM}} &= \sum_{A}^{N_{\text{QM}}}\sum_{B>A}^{N_{\text{QM}}}\frac{Z_A Z_B}{4\pi\varepsilon_0 R_{AB}} \\ &\quad + \sum_{A}^{N_{\text{QM}}}\sum_{K}^{N_{\text{MM}}}\frac{Z_A Q_K}{4\pi\varepsilon_0 R_{AK}} \end{aligned} \tag{72}$$

In addition to electrostatics, there are also Van der Waals interactions between the subsystems that are handled at the force field level (Eq. (69)), as if the QM nuclei were MM atoms. Similar to the previous model, bonded interactions, such as bonds, angles, and torsions involving both QM and MM atoms, are described by the respective force field functions.

If the QM and MM subsystems are connected by chemical bonds, care has to be taken when evaluating the QM wave function. Cutting the QM/MM bond creates one or more unpaired electrons in the QM subsystem. In reality, these electrons are paired with electrons belonging to the atoms on the MM side. A number of approaches to remedy the artefact of such open valences have been proposed. The most easy solution is to introduce a monovalent link atom at an appropriate position along the bond vector between the QM and MM atoms. Hydrogen is most often used, but there is no restriction on the type of the link atom and even complete fragments, such as methyl groups, can be used to cap the QM subsystem. The link atoms are present only in the QM calculation, and are invisible for the MM atoms. Alternative approaches for capping the QM region are the frozen orbital approach (Philipp and Friesner, 1999) and the generalized hybrid orbital method (Gao *et al.*, 1998).

The QM/MM scheme of Field and coworkers provides a conceptually intuitive way of including the effect of an environment on a chemical reaction. However, unless polarization is treated explicitly at the force field level, this QM/MM model is not internally consistent. In most force fields polarization is not explicitly included, but is implicitly accounted for via the parameters in the other terms, most notably, in the nonbonded interactions. Thus, although the MM region can induce polarization of the QM subsystem, the latter cannot back-polarize the MM region. A related problem arises from the use of standard Lennard-Jones and charge parameters, which implicitly contain polarization. When using these parameters without modification, there is both explicit and implicit polarization of the QM region. Therefore, the total polarization can be overestimated. To avoid such possible artefact, the nonbonded parameters in principle should be reparametrized for use in QM/MM simulations. However, this procedure requires the optimization of many parameters that also depend on the level of theory employed for the QM subsystem, and is most often skipped.

3.3
Applications

In this section, we review a number of representative applications of excited state dynamics simulations in the context of photobiology.

3.3.1
Photoreceptor Proteins

3.3.1.1 Retinal Proteins

Response to visible light in higher eukaryotes is mediated by the visual pigment Rhodopsin, which is a seven-helix transmembrane protein located in the photoreceptor rodd cells in the retina. Rhodopsin contains a 11-*cis* retinal molecule that is covalently linked to a lysine residue (Lys296) (Okada *et al.*, 2004), as shown in Figure 3.6). The initial step in the vision process is photoisomerization of this highly conjugated chromophore, which induces strain in the chromophore pocket. Relaxation of

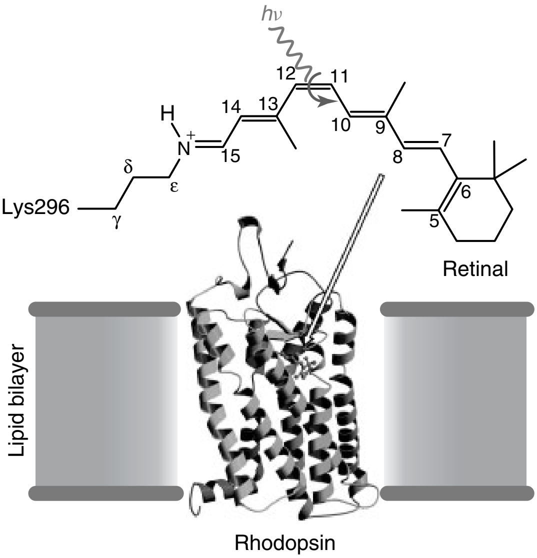

Fig. 3.6 Retinal (a) is covalently linked to a lysine residue in the membrane protein Bovine rhodopsin (b). Photon absorption by retinal induces a *cis*-to-*trans* isomerization of the conjugated $C_{11}{=}C_{12}$ bond that leads to an all-*trans* configuration. For clarity, the membrane is shown only schematically.

this strain is accompanied by conformational changes that ultimately trigger a signal transduction cascade in the cell.

In archaea, all-*trans* retinal isomerization in bacteriorhodopsin is the initial step in converting solar energy into chemical energy. For instance, in *Halobacterium Salinarium*, the conformational strain induced by photoisomerization is used to pump protons across the cell membrane against a concentration (pH) gradient. By controlling the proton flow back into the cell through other membrane proteins, energy is released that is subsequently used to synthesize high-energy compounds. As these examples show, photoisomerization of conjugated chromophores in proteins is a commonly employed theme in nature to allow organisms to respond to and use visible light.

Isolated retinal can undergo photoisomerization around any of its conjugated bonds (Koyama *et al.*, 1991). In contrast, when retinal is embedded in rhodopsin, photoisomerization exclusively takes place around the $C_{11}{=}C_{12}$ bond to form the all-*trans* photoproduct (Figure 3.6) (Mathies and Lugtenburg, 2000). In bacteriorhodopsin, which has a different protein cavity and retinal configuration, photon absorption induces an isomerization from an all-*trans* to 13-*cis* conformation (Tittor and Oesterhelt, 1990). These observations suggest that the protein environment is crucial for photoactivation. However, despite a wealth of structural and spectroscopic data, there is no consensus on how the protein matrix modulates the photochemical properties of retinal to ensure both high efficiency and bond selectivity of the isomerization process.

More than three decades ago, Warshel made the first serious attempt to address this issue. Using the empirical Quantum mechanical Consistent Force Field Method for π electron systems (QCFF/PI) to describe the excited state and a simple restraint on the retinal atoms to model the steric interaction with the protein matrix, he demonstrated that a space-saving photoisomerization reaction occurs, requiring minor rearrangements in the retinal cavity (Warshel, 1976). In a so-called bicycle-pedal mechanism, two double bonds rotate concertedly in opposite directions, such that the overall conformational change is minimized. Since then, Warshel and his coworkers have successively improved the model, employing better structural data and new computational developments (Warshel and Barboy, 1982; Warshel, Chu and Hwang, 1991; Warshel and Chu, 2001). In their most recent work, Warshel and Chu have used an advanced QM/MM strategy, with improved QCFF/PI parameters for the excited state of the chromophore, and polarization of the MM environment, to perform multiple excited state simulations of the photoisomerization event based on a high-resolution X-ray structure of bacteriorhodopsin (Luecke *et al.*, 1999).

The first *ab initio* QM/MM simulation of retinal photoisomerization in the protein environment of bacteriorhodopsin has been reported by Schulten and coworkers in 2003 (Hayashi, Tajkhorshid and Schulten, 2003). A small part of the all-*trans* retinal consisting of eight heavy atoms (C_{11} to C_ε, Figure 3.6), was described at the CASSCF level of theory. For this truncated chromophore, a full active space was used that comprised six electrons in six orbitals. The rest of the chromophore and the protein were modeled with the Amber94 force field. With this model, multiple simulations were carried out that have yielded a consistent picture of the dynamic events that follow photo absorption in the protein.

Very recently, Olivucci and coworkers, in a tremendous computational effort, have performed a QM/MM simulation of the excited state dynamics of retinal in bovine rhodopsin (Frutos *et al.*, 2007). Retinal was modeled at the CASSCF/6-31G* level, with an active space that included a complete π-system of 12 electrons in 12 orbitals. To compensate for the lack of dynamic electron correlation in the CASSCF formalism, the forces were scaled to match the forces evaluated at the CASPT2 level of theory. Surprisingly, a single linear scaling factor sufficed along the complete minimum-energy isomerization pathway. The rest of the protein was described by a modified version of the Amber force field, in which charges on the atoms in the vicinity of the retinal were reparameterized to reproduce the measured excitation wavelength. With this QM/MM model of rhodopsin, a 140 fs trajectory was computed that provided an atomistic description of the electronic and geometrical changes that prepare the system for decay to the ground state.

The simulation studies by Warshel, Schulten, and Olivucci have provided detailed atomistic insights into the sequence of events initiated by photon absorption and have established the role of the protein environment on the isomerization process. Immediately after excitation to S_1, bond-length relaxation takes place that occurs on a time scale of about 10 fs. This initial relaxation phase is followed by a space-saving isomerization process that includes the bicycle-pedal motion. Selectivity is achieved by steric interactions that hinder rotations around other bonds. Furthermore, in the protein environment the chromophore is rapidly channeled toward the seam region. The momentum acquired in the excited state ensures a high isomerization quantum yield after decay (Hayashi, Tajkhorshid and Schulten, 2003; Warshel and Chu, 2001).

Interestingly, recent work by Weingart on an isolated retinal chromophore model has shown that the isomerization quantum yield depends critically on the initial retinal configuration (Weingart, 2007). In the resting state of bovine rhodopsin (Okada *et al.*, 2004) the chromophore is distorted from planarity. By taking this nonplanar retinal structure as a starting point for a series of excited state CASSCF dynamics simulations, Weingart found that in 70% of the trajectories, the all-*trans* photoproduct was formed, in close agreement with the experimentally observed quantum yield. This result suggests that selectivity might originate predominantly from strain imposed by steric interactions between the chromophore and the protein *before* photon absorption.

3.3.1.2 **Photoactive Yellow Protein**

Photoactive yellow protein (PYP) is believed to be the primary photoreceptor for the photo avoidance response of the salt-tolerant bacterium *Halorhodospira halophila* (Hellingwerf, Hendriks and Gensch, 2003). PYP contains a deprotonated 4-hydroxy-cinnamic acid (or *p*-coumaric acid, pca) chromophore linked covalently to the γ-sulphur of Cys69 via a thioester bond (green, Figure 3.7). Upon absorbing a blue-light photon, PYP enters a fully reversible photocycle involving several intermediates on timescales ranging from a few hundred femtoseconds to seconds (Hellingwerf, Hendriks and Gensch, 2003).

By means of QM/MM MD simulations at the CASSCF(6,6)/3-21G level in combination with the Gromos96 force field, the detailed sequence of structural changes that follow photon absorption has been revealed (Groenhof *et al.*, 2004). The crucial step is a light-induced trans-to-cis isomerization of the covalently

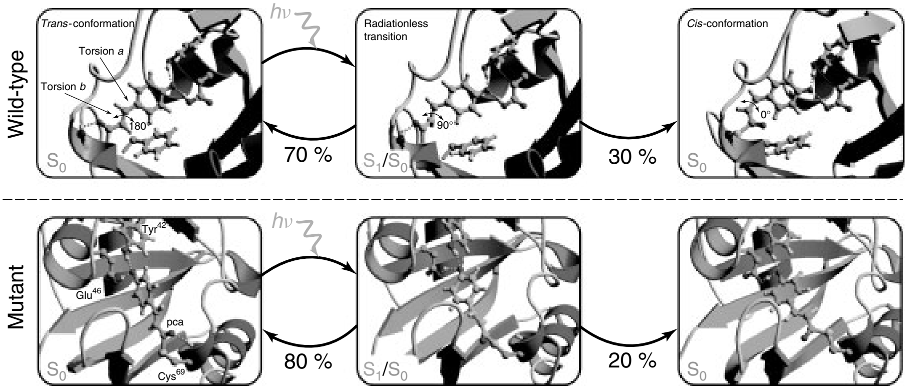

Fig. 3.7 Photochemistry of photoactive yellow protein. Snapshots from excited state trajectories of the (a) wild type , and (b) mutant, showing the chromophore (pca) in the active site pocket. The first snapshot is at the excitation. The second shows the configuration at the radiationless transition from S_1 to S_0. The third snapshot shows the photoproduct. In the wild type, isomerization takes place around the double bond (torsion *b*), whereas in the mutant, a single bond (torsion *a*) rotates. In both systems, the carbonyl oxygen of the thioester linkage flips, causing the break of the hydrogen bond to the backbone of Cys69.

bound chromophore (Figure 3.7). In simulations of an isolated chromophore, no double bond photoisomerization was observed, demonstrating that the protein environment is essential for the photoreaction. Furthermore, mutating one of the key amino acids in the chromophore cavity altered the photochemical reaction and led to a different photoproduct in the simulations (Groenhof *et al.*, 2008). These observations, which are difficult to predict by other means, demonstrate that the photoreactivity of the chromophore is extremely sensitive to the surrounding protein environment.

Figure 3.7 shows the primary events after photoexcitation of the wild-type protein. The chromophore rapidly decays to the ground state via a 90° rotation of the double bond (torsion *b*, Figure 3.7). Upon returning to the ground state the chromophore relaxes back either to the original *trans* conformation (180°), or it continues isomerizing to a *cis* conformation (0°). In the latter case, the relaxation also involves a flip of the thioester linkage, in which the carbonyl group rotates 180°. During this rotation, the hydrogen bond between the carbonyl oxygen and the Cys69 backbone amino group is broken (Figure 3.7). In total, 14 MD simulations were carried out, initiated from different snapshots from a classical ground state trajectory. The fluorescence lifetime (200 fs) and isomerization quantum yield (30%) in the simulations agree well with experiments (400 fs (Mataga *et al.*, 2000) and 35% (Hellingwerf, Hendriks and Gensch, 2003), respectively). Furthermore, it was found that in the protein environment the isomerization is enhanced by a preferential electrostatic stabilization of the chromophore's excited state by the guanidinium group of Arg52, located just above the negatively charged chromophore ring.

PYP mutants in which the arginine has been replaced by an uncharged amino acid can still enter the photocycle, albeit with a lower rate and quantum yield (Changenet-Barret *et al.*, 2007; Takeshita *et al.*, 2002). These findings indicate that Arg52 is important but not essential for photoactivation. To elucidate the role of this arginine in the activation process in more detail, excited state dynamics simulations have been performed on the X-ray structure of the Arg52Gln mutant of PYP (Shimizu *et al.*, 2006). In the mutant, the primary events after photoexcitation are different from those in the wild type (Groenhof *et al.*, 2008). First, the predominant excited state reaction in the mutant involves isomerization of a single bond in the chromophore (torsion *a*, Figure 3.7), rather than the double bond (torsion *b*). Although single bond isomerization does not result in the formation of the *cis* chromophore, a 180° flip of the thioester group and a rupture of the hydrogen bond to Cys69 was observed with a 20% quantum yield (Figure 3.7). Together with the experimental observation that the mutant has a photoactivation quantum yield of about 21% (Takeshita *et al.*, 2002), this suggests that the key step to enter the photocycle is the oxygen flip rather than the double bond isomerization.

To summarize, the simulations are consistent with experimental observations and have provide detailed structural and dynamic information at a resolution well beyond that achievable by other means. From the simulations, key amino acids have been identified and the mechanism by which they control the primary events in the photocycle of PYP. These are (i) photoisomerization around a double or a single bond and (ii) the break of a hydrogen bond between the chromophore and the protein backbone. These events trigger a proton transfer from the protein to the chromophore, which ultimately leads to the signaling state of PYP.

3.3.2
Fluoroproteins

3.3.2.1 Green Fluorescent Protein

The discovery of the green fluorescent protein (GFP) in the early 1960s had a pronounced impact on fluorescence microscopy and ultimately heralded a new era in the bio- and nanosciences. This success is based on the applicability of GFP and its variants as genetically encodable fusion tags that enable to monitor protein localizations and dynamics in live cells (Lippincott-Schwartz, Altan-Bonnet and Patterson, 2003; Miyawaki, Sawano and Kogure, 2003; Tsien, 1998). Recently, a new class of green fluorescent protein (GFP)-like proteins has been discovered, which can be reversibly photoswitched between a fluorescent (*on*) and a nonfluorescent (*off*) state (Ando, Mizuno and Miyawaki, 2004; Chudakov *et al.*, 2003a; Lukyanov *et al.*, 2000; Habuchi *et al.*, 2005; Wilmann *et al.*, 2006; Dedecker *et al.*, 2006). As the reversible photoswitching of photochromic organic molecules such as fulgides or diarylethenes is usually not accompanied by fluorescence (Crano and Guglielmetti, 1999), this switching reversibility is a very remarkable feature that may allow new applications. For example, the reversible photoswitching, also known as *kindling*, may provide nanoscale resolution in far-field fluorescence optical microscopy much below the diffraction limit (Hell, Jakobs and Kastrup, 2003; Hell, 2003a; Hell, Dyba and Jakobs, 2004; Hofmann *et al.*, 2005; Geisler *et al.*, 2007). Since fluorescence can be sensitively read out from a bulky crystal, the prospect of erasable three-dimensional data storage is equally intriguing (Sauer, 2005). Below, we will detail the excited state molecular dynamics of the GFP-like protein asFP595 as a prototype for a reversibly switchable fluorescent protein.

The GFP chromophore has been studied extensively, both by means of experimental and theoretical methods (Remington, 2006; Helms, 2002; Zimmer, 2002). Figure 3.8a shows the GFP protein with its β-barrel fold (Yang, Moss and Phillips, 1996; Ormö, Cubitt *et al.*, 1996). The chromophoric moiety is buried in the center of the protein structure. The *p*-hydroxybenzylidene-imidazolinone chromophore, shown in Figure 3.8b, is formed upon maturation of the protein in an autocatalytic cyclization–oxidation reaction of a tripeptide (Ser-Tyr-Gly in the *Aequorea victoria* wild type). The chromophore is embedded in the protein matrix and is surrounded by ionizable residues. Notably, this polar environment does not significantly change the absorbance of the chromophore as compared to the solution or the gas phase. The wild-type GFP exhibits two main absorption bands at 398 and 477 nm, which were assigned to the neutral and anionic chromophore species, respectively (Schellenberg *et al.*, 2001; He, Bell and Tonge, 2002; Bell *et al.*, 2003). However, the former absorption could also be due to the cationic chromophore (Voityuk, Michel-Beyerle and Rosch, 1998a; Dong, Solntsev and Tolbert, 2006). The GFP protein fluoresces with a high quantum yield of about 80% and a fluorescence

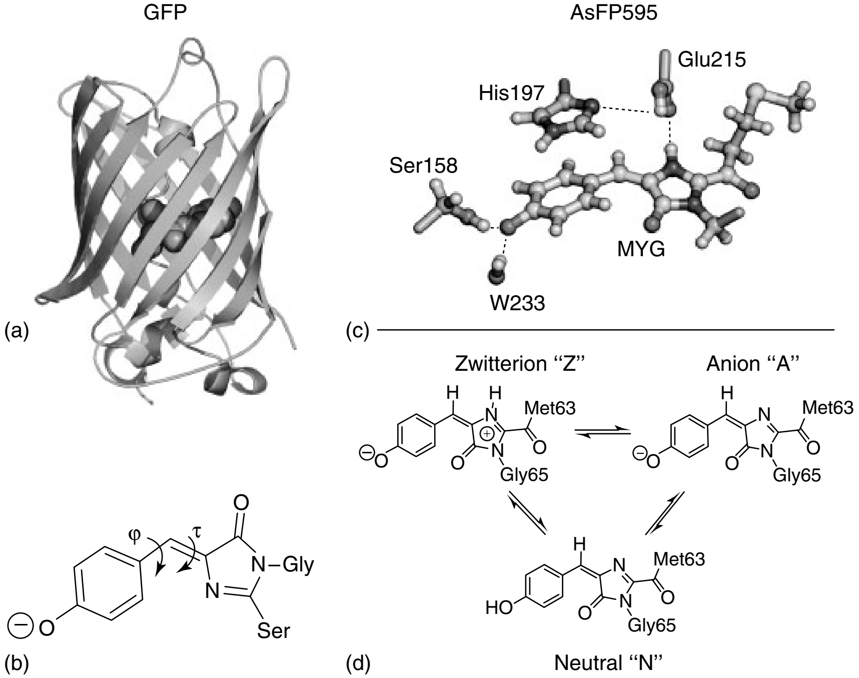

Fig. 3.8 Fluorescent proteins GFP and asFP595. (a) X-ray structure of GFP (PDB entry 1EMB), Ref. Brejc *et al.* (1997), with the β-barrel fold shown in green and the chromophore (in the center of the protein) in orange spheres. (b) Schematic drawing of the anionic form of the *cis* *p*-hydroxybenzylidene-imidazolinone chromophore. (c) The asFP595 chromophore (MYG) in the *trans* conformation and adjacent amino acid side chains. Dashed lines represent hydrogen bonds between MYG and Ser158, Glu215, and a crystallographic water molecule (W233), respectively. His197 is π-stacked to the MYG phenoxy-moiety and forms a hydrogen bond to Glu215. The carbon skeleton of the quantum mechanical (QM) subsystem is shown in cyan, and the carbon atoms modeled by molecular mechanics (MM) are shown in orange. (d) Schematic drawings of the important MYG protonation states. (Please find a color version of this figure on the color plates.)

lifetime of about 3 ns (Tsien, 1998); Striker *et al.*, 1999). Recent time-resolved Fourier transform infrared (tr-FTIR) measurements (Stoner-Ma *et al.*, 2005, 2006) together with classical molecular dynamics simulations (Lill and Helms, 2002) and static *ab initio* calculations (Vendrell *et al.*, 2006) suggest that in the protein, the fluorescent anionic chromophore species is formed out of the neutral species in a three-step excited state proton transfer (ESPT) reaction that involves a serine, a water molecule, and a glutamic acid residue that form a proton wire in the chromophore pocket (Agmon, 2005; Leiderman, Huppert and Agmon, 2006).

In contrast to the protein, model chromophores in solution do not feature fluorescence. Instead, after excitation, fast ground state recovery on the picoseconds timescale is observed (Webber, Litvinenko and Meech, 2001; Litvinenko, Webber and Meech, 2001).

Static calculations of vertical excitation energies and minimum-energy conical intersections and reaction paths have been carried out using *ab initio* (Martin, Negri and Olivucci, 2004; Altoe *et al.*, 2005; Sinicropi *et al.*, 2005), density functional (Marques *et al.*, 2003; Laino, Nifosi and Tozzini, 2004; Patnaik *et al.*, 2007), and *semiempirical* methods (Voityuk, Michel-Beyerle and Rosch, 1998b; Weber *et al.*, 1999; Voityuk *et al.*, 2001; Toniolo, Granucci and Martinez, 2003). The computational efficiency of *semiempirical* methods, in conjunction with a careful parameterization against *ab initio* data, enabled Toniolo *et al.* to carry out multiple-spawning nonadiabatic molecular dynamics simulations of the neutral chromophore, both in the gas phase and microsolvated in a small water droplet (Toniolo *et al.*, 2004; Martinez, 2006; Levine and Martinez, 2007). The simulations showed that the aqueous environment alters the topology of the involved electronic states such that the minimum energy S_0/S_1 conical intersection becomes the global minimum on S_1, thus accounting for the observed ultrafast ground state recovery. In addition, the authors predict a space-saving hula-twist *cis-trans* isomerization of the chromophore, that is, a simultaneous rotation around the ring-bridging torsions ψ and τ in Figure 3.8b. MD simulations based on a simple MM forcefield description of the excited state potential energy surface suggest a similar chromophore isomerization mechanism in the E2-GFP mutant (Nifosi and Tozzini, 2006).

3.3.2.2 **asFP595**

The fluoroprotein asFP595, a GFP-like protein that is expressed in the sea anemone *Anemonia sulcata*, converts absorbed green light of $\lambda_{\text{abs,max}} =$ 568 nm into a red fluorescence emission at $\lambda_{\text{fl,max}} = 595$ nm (Chudakov *et al.*, 2003a,b; Lukyanov *et al.*, 2000; Andresen *et al.*, 2005). The fluorescence quantum yield of asFP595 is very low (Lukyanov *et al.*, 2000, 2005), and subpicosecond ground state recovery without any structural damage is usually observed (Schüttrigkeit *et al.*, 2006). These photochemical properties suggest that the fluoroprotein might function as an efficient and stable sun blocker that protects the anemone against photodamage (Salih *et al.*, 2000). Remarkably, and in contrast to most other fluorescent proteins known so far, fluorescence of asFP595 can be reversibly and selectively switched *on* and *off* in response to irradiation of a particular wavelength (Andresen *et al.*, 2005). Analysis of the X-ray crystal structures (Andresen *et al.*, 2005) showed that this *on-off* switching of the fluorescence is accompanied by a *trans-cis* isomerization of the protein's chromophore, a 2-acetyl-5-(*p*-hydroxybenzylidene)-imidazolinone moiety formed autocatalytically from a Met-Tyr-Gly (MYG) tripeptide (Figure 3.8c).

The reversible photoswitching of asFP595 may allow fundamentally new applications. For example, as recently demonstrated by Hofmann and coworkers, asFP595 can provide nanoscale resolution in optical microscopy much below the diffraction limit (Hofmann *et al.*, 2005). Today, however, the photochromic properties of asFP595 still leave much room for improvement. To systematically exploit the potential of such switchable proteins and to enable a rational improvement of their properties, a detailed molecular understanding of the switching process is mandatory. Theoretical methods, in particular excited state molecular dynamics simulations, can yield the required atomistic insights into the photoswitching mechanism. Static quantum chemical calculations were carried out to predict vertical excitation energies of asFP595 model chromophores in the gas phase and in a continuum dielectric model (Amat *et al.*, 2006; Nemukhin, Topol and Burt, 2006) as well as in a minimal protein environment, the latter by means of QM/MM calculations (Grigorenko *et al.*, 2006).

In a two-step approach, QM/MM simulations were used to study the photoswitching mechanism of asFP595. First, because the positions of the protons were not resolved in the available X-ray structures, the aim was to locate the protons in the chromophore binding pocket. To this end, simulated UV/Vis spectra were compared to the available experimental data. This comparison was backed up by continuum electrostatics calculations, and enabled to unambiguously determine the protonation of the *on* and *off* states of asFP595 (Schäfer *et al.*, 2007). These calculations ascertained that the neutral chromophore form is dominant in the *cis* conformation (*on*-state), whereas the zwitterionic and the anionic chromophores predominate in the *trans* conformation (*off*-state) (Figure 3.8d). These results reveal that the photoinduced *trans–cis* isomerization of the chromophore is accompanied by proton transfer events. As shown in Figure 3.8c, these proton transfers are mediated by the ionizable residues Ser158, His197, and Glu215 in the chromophore pocket. His197 is connected through an extended hydrogen bonding network to the exterior interface between the protein and the surrounding solution (not shown in Figure 3.8).

In the second step of the study, nonadiabatic QM/MM molecular dynamics simulations were carried out to elucidate the photochemistry of each of the previously identified protonation states of the chromophore (Schäfer *et al.*, 2008). In these simulations, energies and gradients on the ground- and excited state were calculated on the fly at the CASSCF(6,6)/3-21G level of theory. Prior to the dynamics simulations, minima and conical intersections were characterized in vacuo at the RASSCF(18,7+4+5)[2,2]/6-31G* level of theory, that is, including all π-orbitals of the chromophore in the active space. The final six electron, six orbital active space used in the QM/MM dynamics simulations was selected from these RASSCF calculations such as to enable the simultaneous description of the ground state and the first excited state.

The quantum yields and excited state lifetimes from the QM/MM dynamics simulations agree well with experimental measurements (Schüttrigkeit *et al.*, 2006). In addition, the simulations enable to predict the structures of the hitherto unknown photochemical intermediates and the irreversibly fluorescent state. Furthermore, the simulations revealed how the proton distribution in the active site of the asFP595 controls the photochemical conversion pathways of the chromophore in the protein matrix. The suggested mechanism in Figure 3.9 shows that changes in the protonation state of the chromophore and some proximal amino acids lead to different photochemical states, which all turn out to be essential for the photoswitching mechanism. These photochemical

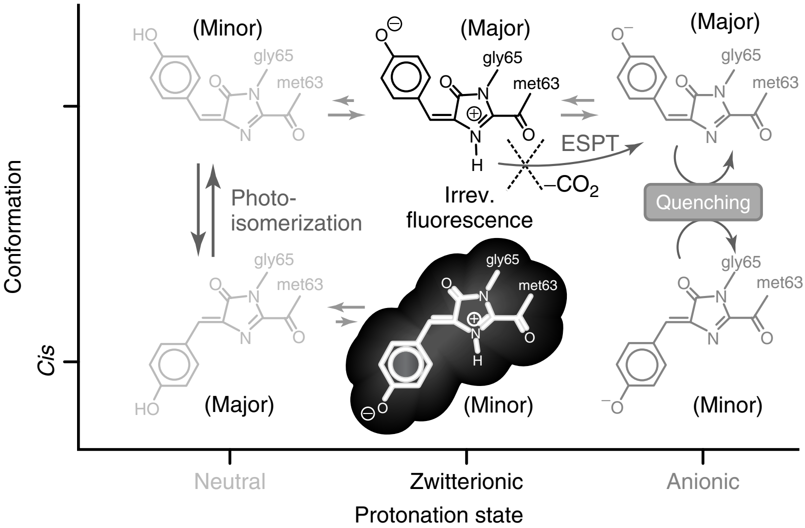

Fig. 3.9 Scheme of the reversible photoswitching mechanism of asFP595. The fluorescent state Z_{cis} is highlighted. The green arrows indicate ground state equilibria, whereas the red arrows indicate excited state processes. The major protonation states are the zwitterionic and the anionic chromophores in the *trans* conformation, and the neutral chromophore in the *cis* conformation, as indicated in the square brackets. (Please find a colour version of this figure on the color plates.)

states are (i) a neutral chromophore, which can photoisomerize back and forth between the *trans* and *cis* configuration on a subpicosecond timescale; (ii) an anionic chromophore, which rapidly undergoes radiationless decay after excitation in both the *cis* and *trans* configuration; and (iii) a long-lived and therefore putatively fluorescent zwitterionic chromophore. The *trans* zwitterion can rapidly return to the ground state through proton transfer to the neighboring Glu215 (Figure 3.8c). This alternative de-excitation pathway is not accessible for the *cis* isomer, thus explaining why only the *cis* form fluoresces. The overall stability (and thus the relative population) of the different protonation states is controlled by the isomeric state of the chromophore.

On the basis of the simulations, it was proposed that radiation-induced decarboxylation of the glutamic acid Glu215 could block the proton transfer pathways that enable the deactivation of both the *cis* and *trans* zwitterions and thus leads to irreversible fluorescence (Figure 3.9). Recent experiments on the structurally similar protein Dronpa (Habuchi *et al.*, 2006; Fron *et al.*, 2007) also provide strong support for the proposed protonation/deprotonation mechanism. The similarity between the chromophores in a variety of fluoroproteins suggests that during molecular evolution, the (*p*-hydroxybenzylidene)imidazolinone chromophoric moiety served as a template and that the photochromic properties – and thus the function – was fine-tuned by the protein environment.

3.3.3
Photochemistry of DNA

Deoxyribonucleic acid (DNA) carries the genetic information of all cellular forms of life. DNA forms a double helix, in which the nucleoside bases of the single strands are stacked upon each other, forming strong hydrogen bonds with the bases in the complementary strand (Watson–Crick configuration). Owing to the high absorbance of the bases in the harmful ultraviolet (UV) region of the spectrum, DNA is vulnerable to photochemical damage that can ultimately lead to cancer. To study the effects of UV radiation on DNA, molecular dynamics simulations have been performed of the ultrafast processes that follow photon absorption.

The fastest photochemical reaction involving base pairs in opposite strands was found to be proton transfer (Abo-Riziq *et al.*, 2005; Schwalb and Temps, 2007). Figure 3.10 shows the sequence of events that follows excitation of a cytosine–guanine base pair in DNA. According to the QM/MM simulations at the CASSCF(8,8)/3-21G level of theory (see Figure 3.5, for details on the QM/MM partitioning), photon absorption induces transfer of a proton from the guanine to the cytosine (Groenhof *et al.*, 2007). This proton transfer enhances ultrafast decay of the excited state. After the radiationless transition to the ground state, the original Watson–Crick configuration is quickly restored. The entire photochemical reaction is completed within 200 fs. The absorbed energy is converted into heat and therefore does not lead to structural damage. These findings have been recently corroborated by experimental observations (Schwalb and Temps, 2007; Miannay *et al.*, 2007). The existence of an ultrafast deactivation channel involving the observed proton transfer had been proposed previously by Sobolewski and Domcke on the basis of static high level *ab initio* computations (Sobolewski and

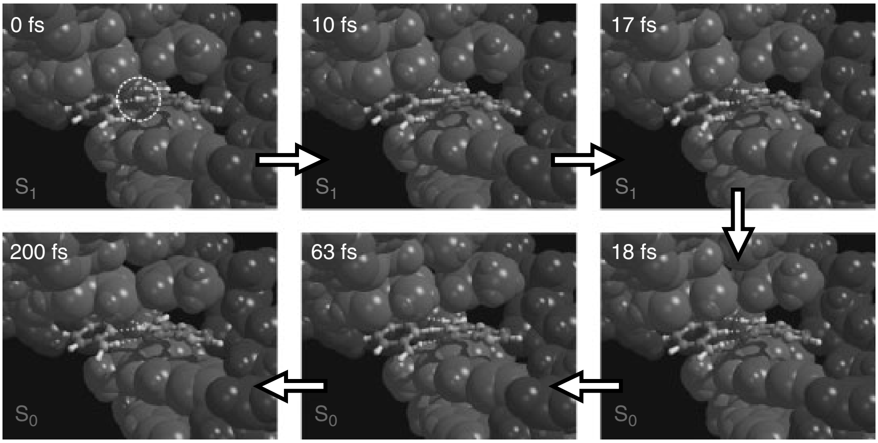

Fig. 3.10 Excited state dynamics of a Watson–Crick cytosine–guanine base pair after light absorption. The frames show the light-induced transfer of the central proton from a guanine to a cytosine. After this transfer, a radiationless transition to the ground state takes place (18 fs). The proton then rapidly returns to the guanine, restoring the Watson–Crick base pair (200 fs).

Domcke, 2004; Sobolewski, Domcke and Hättig, 2005).

Radiationless decay occurs along an extended hyperline that lies parallel to the proton transfer coordinate in the vicinity of the excited state minimum, as shown in Figure 3.11. The gradient difference vector and the derivative coupling vector (Eq. (27)) are colinear and thus span a one-dimensional branching space. The seam is displaced from the proton transfer pathway along a skeletal deformation of the bases. Decay can thus occur anywhere along the single proton transfer coordinate, accounting for the remarkably short lifetime of the excited base pair (Abo-Riziq *et al.*, 2005; Schwalb and Temps, 2007). In vacuum, decay occurs after a complete proton transfer, whereas in DNA decay can also occur much earlier. The origin of this effect lies in the temporal electrostatic stabilization of the dipole in the excited state by the solvated DNA environment. The seam topology also accounts for the recrossings (partial diabatic trapping) that were observed in the MD simulations. As schematically shown in Figure 3.11, vibrational motions perpendicular to the reaction coordinate repeatedly drive the system in and out of the conical intersection, until the base pair eventually returns to its stable ground state minimum.

3.3.4
Summary and Outlook

Understanding light-driven processes is one of the major goal of the bio- and nanosciences. The underlying molecular mechanisms are typically governed by subpicosecond atomic motions. Mechanisms on such ultrafast timescales are very challenging to probe by experiment. Here, molecular dynamics simulations have become an invaluable tool to understand such processes in atomic detail.

In this article, we have reviewed the state of the art in excited state molecular dynamics simulations. In the

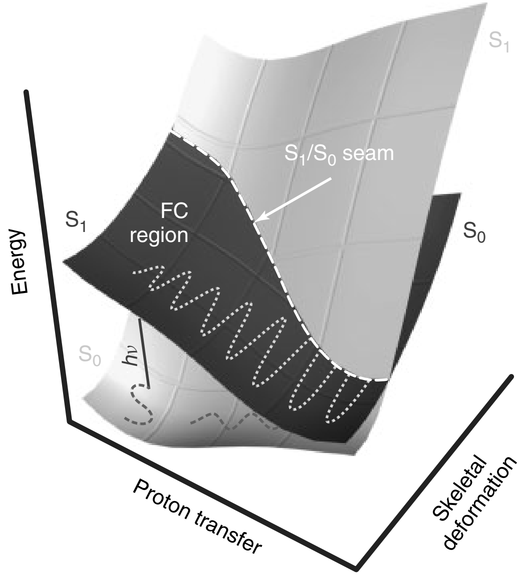

Fig. 3.11 Artist impression of the potential energy surfaces of the excited (S_1) and ground (S_0) states of the cytosine–guanine base pair versus protein transfer and skeletal deformation of the bonds. The dashed yellow and green lines represent the path sampled in a typical trajectory. Motion along the proton transfer coordinate connects the Franck-Condon geometry to the minimum of the S_1 state. Nonradiative decay occurs along the intersection seam between the surfaces. Note that the trajectory encounters the seam more than once and recrosses between the excited and ground states repeatedly. (Please find a color version of this figure on the color plates.)

applications that we have selected here, the simulations could provide detailed structural and dynamical information of the photobiological process at a resolution well beyond what is achievable experimentally. The applications also demonstrate what is feasible today with on-the-fly molecular dynamics simulations, and where the limits are. These limits are predominantly imposed by the current state of computer technology, which restricts both system size and timescale of the processes studied. However, the expected increase of computer power, complemented by the development of more efficient electronic structure methods and new algorithms, will enable the study of larger systems and longer timescales in the near future. Therefore, excited state molecular dynamics simulation has the potential to ultimately lead to a better understanding of photobiological reactions. Furthermore, the simulations will enable the prediction of photochemical properties and aid the rational design of new photoactive systems.

4.1
Time-Dependent DFT

In the following, a time-dependent, quantum mechanical treatment of many-body systems, for example large molecules and atomic cluster, is proposed and formulated in terms of evolution equations (Bang and Bohr, 2008). For that purpose, the density functional theory (DFT) formalism is reformulated into a framework of currents so as to give the energy a parameter-dependent behavior, of, for example, time, which allows for following trajectories of the electrons. Furthermore, a more rigorous form of the exchange potentials is incorporated. The current formalism is describing the transition of electrons from one orbital to another. The formalism is also extended to the relativistic region.

4.1.1
Introduction

At the present time, electronic structure calculations of larger molecules are the focus of intense scientific activity. Here, DFT plays a prominent role of being the most used framework for performing quantum calculations of large molecular systems such as biomolecules. However, electronic calculations of giant biomolecules, for example, protein complexes and membrane systems, which are of interest for researchers in biotechnology, are difficult to be carried out in a quantum mechanical setting with the present- day techniques (Bohr, Jalkanen, *et al.*, 1999). They comprise, for example, the standard DFT computer programs that have been very successful in dealing with smaller molecules. This is also due to the fact that the many-body Schrödinger equation is very complicated to solve since it involves many coupled partial differential equations. We shall, as being explained in the following, instead be using the equations for electronic currents and the corresponding continuity equations that, with the help of vector algebra, lead to simple evolution equations for several electrons (Davidov, 1965). In the following, we shall first briefly mention some of the celebrated methods used today before explaining our own method.

4.1.2
The Standard DFT Formalism

The most prominent aim of the methods of quantum molecular calculations is to solve and obtain electron orbitals in molecules. We shall in the later chapters

Handbook of Molecular Biophysics. Methods and Applications. Edited by Henrik G. Bohr.
Copyright © 2009 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim
ISBN: 978-3-527-40702-6

show various approaches to that. In this section, we shall, however, review some of the standard features of DFT with the usual equations (Atkins and Friedman, 1997) before we develop new tools.

Ordinarily, the DFT formalism for large molecules is formulated as follows:

One starts with the energy, $E(\rho)$, as a function of the density of charged particles (electrons):

$$E(\rho) = -\frac{\hbar^2}{2me}\sum_{i=1}^{n}\int \Psi_i^*(r_1)\nabla^2\Psi_i(r_1)dr_1 - \sum_{I=1}^{N}\int \rho(r_1)\frac{Z_I e^2}{4\pi\varepsilon_o r_{I1}}dr_1 + \int \frac{\rho(r_1)\rho(r_2)e^2}{4\pi\varepsilon_o r_{I2}}dr_1 dr_2 + E_{XC}[\rho] \tag{1}$$

where the one-electron orbitals Ψ_i are the Kohn–Sham (KS) orbitals that satisfy the equation of motion:

$$\left\{-\frac{\hbar}{2m_e}\nabla_1^2 - \sum_{I=1}^{N}\frac{Z_I e^2}{4\pi\varepsilon_o r_{I1}} + \int dr_2 \times \frac{\rho(r_2)e^2}{4\pi\varepsilon_o r_{I2}} + V_{XC}\right\}\Psi_i(\mathbf{r}_1) = \varepsilon_i\Psi_i(\mathbf{r}_1) \tag{2}$$

The energy function is given as a function of the charge density at the exact ground state at the location $\mathbf{r}$ and this charge density is given by

$$\rho(\mathbf{r}) = \sum_{i=1}^{n}|\Psi_i(\mathbf{r})|^2 \tag{3}$$

In the energy expression above, the first term represents the kinetic energy of the electrons, the second term represents the interaction term between the nuclei (with index I and atomic number Z_I), and the third term being the Coulomb interaction between the electron charges of the one-electron orbitals with indices i ($i = 1, 2, \ldots$). The term ε_i is the KS orbital energies, and V_{XC} is the exchange correlation (xc) potential, which is a functional derivative of the xc energy $V_{XC}(\rho) = \frac{\delta E_{XC}}{\delta\rho}$, which means that if E_{XC} is known then V_{XC} can be obtained. The KS orbitals in the DFT formalism have the advantage that they allow the density, ρ, to be computed from the equations above. All the equations should be satisfied to ensure self-consistency.

The usual procedure for running a DFT procedure is first to guess the charge density of a certain molecular system where we use a superposition of our atomic densities. Secondly, we use some approximate form for the functional dependency of E_{XC} on the density, which then allows us to calculate the potential $V_{XC}(\rho)$ as a function of r. Next, one is in the position to get the first iterative estimate of the KS orbitals by solving the equations of motion. From these preliminary KS orbital values, one can compute an improved density from the expression for the charge density in terms of the orbitals. Such a procedure is repeated until the density and the xc energy have converged to within a certain tolerance. Finally, the total electronic energy $E(\rho)$ can be computed from Eq. (1). In each step of the procedure, the KS orbitals are numerically calculated and can be expressed in terms of an expansion in a set of basis functions whose coefficients are basically determined once, solving the equation of motion above. The computational time for DFT scales as the third power of the number of basis functions, the latter, thus, being the crucial number in the quantum calculations. An important step in this procedure is to come up with a good choice for the density and thus for the xc energy. We shall come back to that in the next sections. Let us first make a mathematical proposal for a useful xc energy in the following section.

4.1.3
An Expression for the Exchange Correlation Energy

Let us briefly mention an earlier derivation of an xc expressed as a difference, $W = V - V_H$, between the total potential V and the Hartree potential V_H, and with the help of a new central potential term, also used by Talman and Shadwick, see Bang and Hansteen (2002). We may then write

$$W = \sum_i \sum_{j\neq i} \int d\mathbf{r}'^3 \int d\mathbf{r}''^3 \frac{\psi_i(\mathbf{r})^* \psi_j(\mathbf{r})}{E_j - E_i} \times 2 \sum_k \frac{\psi_j(\mathbf{r}')^* \psi_k(\mathbf{r}') \psi_k(\mathbf{r}'')^* \psi_i(\mathbf{r}'')}{\mid \mathbf{r}' - \mathbf{r}'' \mid} \tag{4}$$

which can be simplified using the same restriction on the indices of Coulomb matrix elements, as in Bang and Hansteen (2002):

$$W = C \sum_i \sum_{j\neq i} \sum_k \frac{\psi_i(\mathbf{r})^* \psi_j(\mathbf{r})}{E_i - E_j} \times \int dr' \frac{(\mathbf{j}^L_{jk}(\mathbf{r}') \cdot \mathbf{j}^L_{ki}(\mathbf{r}'))}{(E_k - E_i)(E_j - E_k)} \tag{5}$$

where C is a constant that contains Planck's constant, $C = \hbar 8\pi$. It is quite remarkable that one can obtain such relatively simple expression for the xc. This is a contribution between different orbitals or quantum states i, j. In the case of $E_i = E_j$, this term vanishes and we are left with the zeroth-order Born term. For details, see Bang and Hansteen (2002).

4.2
A Framework for Describing Time Development of Electronic Structures

We shall discuss an alternative to the standard DFT for the description of *electron* motion of states of large, mainly organic, molecules. DFT, developed particularly by Kohn, Hohenberg, and Sham has proved efficient in many cases, and its use needs no further justification. Among the many formulations of this, we shall particularly keep near to that of Gross *et al.* (1996). As mentioned earlier, our foremost desire is to construct the time development of the electronic structural configurations in large molecules leading to an understanding of the electron trajectories.

First, we shall briefly mention a proof for the time dependence of the KS equation, which makes use of the currents as time derivatives of the densities, as explained in Gross *et al.* (1996). It is these currents that later in the text constitute our evolution equations for the electrons. However, in the proof of the KS Density Functional theorem, Gross *et al.* (1996), rather start with the currents and their continuity equation and then rederive the densities in time and space that satisfy the KS equation.

We start, as in Gross *et al.* (1996), with the usual equation of motion for the expectation value of a time-dependent operator, $\hat{O}(t)$:

$$\frac{\partial}{\partial t}\left\langle \Psi_1 \mid \hat{O}(t) \mid \Psi_0 \right\rangle = \left\langle \Psi_1 \left| \frac{\partial \hat{O}}{\partial t} - \mathrm{i}\left[\hat{O}(t), \hat{H}(t)\right] \right| \Psi_0 \right\rangle \tag{6}$$

where we, instead of considering a fixed orbital $\Psi(t)$, consider transitions from orbital 0 to 1. We can now consider a current density $\hat{\mathbf{j}}(r)$ as the operator, $\hat{O}$, and hence obtain

$$\begin{aligned}\frac{\partial}{\partial t}\mathbf{j}(r,t) &= \frac{\partial}{\partial t}\left\langle \Psi_1 \mid \hat{\mathbf{j}}(r) \mid \Psi_0 \right\rangle \\ &= -\mathrm{i}\left\langle \Psi_1 \mid [\hat{\mathbf{j}}(r), \hat{H}(t)] \mid \Psi_0 \right\rangle\end{aligned} \tag{7}$$

and taking two different KS potentials $V_0(t, r)$ and $V_1(t, r)$ with corresponding currents $\mathbf{j}_0(r, t)$ and $\mathbf{j}_1(r, t)$ we can, as in Gross *et al.* (1996), obtain the corresponding densities $n_0(r)$ and $n_1(r)$ from the following equation:

$$\begin{aligned}&\frac{\partial}{\partial t}(\mathbf{j}_a(r,t) - \mathbf{j}_b(r,t)) \\ &= -\mathrm{i}\left\langle \Psi_1 \mid \left[\hat{\mathbf{j}}(r), \hat{H}_a(t) - \hat{H}_b(t)\right] \mid \Psi_0 \right\rangle \\ &= -n_{10}(r)\mathbf{\nabla}(V_a(r,t) - V_b(r,t))\end{aligned} \tag{8}$$

The usual current densities are obtained with $\Psi_0 = \Psi_1$. An important relation between the currents and the densities is manifested in the continuity equation for different densities n, n':

$$\begin{aligned}&\frac{\partial}{\partial t}(n(r,t) - n'(r,t)) \\ &\quad = -\mathbf{\nabla}\cdot(\mathbf{j}(r,t) - \mathbf{j}'(r,t))\end{aligned} \tag{9}$$

The potentials, V, are generally written as an effective potential V_{ef}, containing a time- dependent external potential, a Hartree term as a function of densities $n(r, t)$ and an xc part, V_{XC}:

$$V_{\text{ef}} = V(r,t) + \int d^3r' \frac{n(r',t)}{r-r'} + V_{XC} \tag{10}$$

We will finally make use of a time-dependent KS equation formulated for currents instead of the usual KS orbitals:

$$\begin{aligned}&\frac{\partial}{\partial t}\mathbf{j}(r,t) = \dot{n}\nabla\varphi - n\nabla\frac{\delta E}{\delta n} \approx -n\nabla\frac{\delta E}{\delta n}, \\ &\quad \mathbf{j}(r,t) = n\nabla\varphi, \qquad (11) \\ &E = \int d^3r\left(\frac{1}{2}n(\nabla\varphi)\cdot(\nabla\varphi)\right. \\ &\qquad \left. + (\nabla\sqrt{n})\cdot(\nabla\sqrt{n}) + Vn\right)\end{aligned}$$

where the current density $\mathbf{j}(r, t)$ is connected to the KS orbitals $\Phi(r, t)$ by the equation

$$\begin{aligned}\mathbf{j}(r,t) &= \frac{1}{2i}(\Phi^*(r,t)\mathbf{\nabla}\Phi(r,t) \\ &\quad - \Phi(r,t)\mathbf{\nabla}\Phi^*(r,t)) \\ &= \Phi(r,t)\Phi^*(r,t)\nabla\varphi(r,t)\end{aligned} \tag{12}$$

The previous discussion applies to single electron motion, $\varphi(r, t)$, being the argument of $\Phi(r, t)$. Thus, we obtain transition charge densities that can be compared to electromagnetic transition amplitudes as in Gross *et al.* (1996).

However, the presented expression for the current applies only to single electron processes. The time development of a many-electron system requires the following analysis.

According to KS ideas, we consider an arbitrary density $n(x)$ and the best wave function in a variational sense, such that

$$\left\langle \Psi \middle| \hat{n}(x) \middle| \Psi \right\rangle = n(x) \tag{13}$$

where $\hat{n}(x)$ is the density operator,

$$\hat{n}(x) = \sum_{j=1}^{N} \delta(x - x_j) \tag{14}$$

Since H and $\hat{n}(x)$ are time even, $|\Psi\rangle$ is also time even. The equilibrium density $n_0(x)$ and the associated wave function

$|\Psi_0\rangle$ are obtained by minimizing the energy functional $E(n) = \langle\Psi|H|\Psi\rangle$, that is, $n_0(x)$ is the solution of $\delta E[n]/\delta n = 0$. The ground state wave function $|\Psi_0\rangle$ is stationary, but, for $n(x) \neq n_0(x)$, the wave function $|\Psi\rangle$ is not stationary, so that, in time, it will acquire time odd components. Given a time even wave function $|\Psi\rangle$, the wave function $\exp(\mathrm{i}P)|\Psi\rangle$, where P is an arbitrary *time odd* operator, is also time even. Time odd components are introduced into the time even wave function $|\Psi\rangle$ through a *time even* Hermitian operator Q, that is $|\Psi_Q\rangle = \exp(-\mathrm{i}Q)|\Psi\rangle$ contains time odd components. Of course, the time evolution of $|\Psi_Q\rangle$ is determined by the Schrödinger equation

$$\mathrm{i}\frac{\partial}{\partial t}|\Psi_Q\rangle = H|\Psi_Q\rangle \tag{15}$$

or by the quantum mechanical Lagrangian

$$\mathcal{L} = \frac{\mathrm{i}}{2}\left(\langle\Psi_Q|\dot{\Psi}_Q\rangle - \langle\dot{\Psi}_Q|\Psi_Q\rangle\right) - \langle\Psi_Q|H|\Psi_Q\rangle \tag{16}$$

Let us consider small deviations from equilibrium, so that $n(x) \neq n_0(x)$, but $\delta n(x) = n(x) - n_0(x)$ is small and $|\Psi\rangle$ is close to $|\Psi_0\rangle$. Moreover, Q is small. Expanding in powers of Q, we have, to leading order,

$$\frac{\mathrm{i}}{2}\left(\langle\Psi_Q|\dot{\Psi}_Q\rangle - \langle\dot{\Psi}_Q|\Psi_Q\rangle\right) \approx \frac{\mathrm{i}}{2}\left(\langle\Psi|\dot{\Psi}\rangle - \langle\dot{\Psi}|\Psi\rangle\right) + \langle\Psi|\dot{Q}|\Psi\rangle \tag{17}$$

$$\langle\Psi_Q|H|\Psi_Q\rangle \approx \frac{1}{2}\langle\Psi_0|[[Q, H], Q]|\Psi_0\rangle + \langle\Psi|H|\Psi\rangle \tag{18}$$

Notice the replacement of $|\Psi\rangle$ by the ground state wave function $|\Psi_0\rangle$ in $\langle\Psi|[[Q, H], Q]|\Psi\rangle$, which is consistent with the assumption of small deviations from equilibrium and of the smallness of Q. Since $|\Psi\rangle$ is time even, it follows that $\langle\Psi|\dot{\Psi}\rangle$ is real and $\langle\Psi|\dot{\Psi}\rangle - \langle\dot{\Psi}|\Psi\rangle = 0$ Thus, the Lagrangian for small fluctuations reads

$$\mathcal{L} = \langle\Psi|\dot{Q}|\Psi\rangle - \frac{1}{2}\langle\Psi_0|[[Q, H], Q]|\Psi_0\rangle - \langle\Psi|H|\Psi\rangle \tag{19}$$

As a natural and simple approximation, we set

$$Q = -\sum_{i=1}^{N}\phi(x_i, t) \tag{20}$$

It follows that

$$\begin{aligned}\langle\Psi|\dot{Q}|\Psi\rangle &= -\int dx\,\dot{\phi}\,n,\\ \langle\Psi_0|[[Q, H], Q]|\Psi_0\rangle &= \frac{1}{2}\int dx\,n_0\,(\nabla\phi)(\nabla\phi),\\ \langle\Psi|H|\Psi\rangle &= E[n]\end{aligned} \tag{21}$$

Finally,

$$\mathcal{L} = -\int dx\dot{\phi}n - \frac{1}{2}\int dx(\nabla\phi) \times (\nabla\phi)n_0 - E[n] \tag{22}$$

The equations of motion are written as

$$\dot{\phi} = -\frac{\delta E[n]}{\delta n}, \quad \dot{n} = -\nabla(n_0\nabla\phi) \tag{23}$$

The current operator reads

$$\hat{\mathbf{j}}(x) = -\frac{\mathrm{i}}{2}\sum_{j=1}^{N} \times\left(\delta(x - x_j)\nabla_j + \nabla_j\delta(x - x_j)\right) \tag{24}$$

Thus,

$$\begin{aligned}\mathbf{j}(x) &= \left\langle \Psi_Q | \hat{\mathbf{j}}(x) | \Psi_Q \right\rangle \\ &= i \left\langle \Psi | [\hat{\mathbf{j}}(x), Q] | \Psi \right\rangle \\ &= n_0(x) \nabla \phi(x) \end{aligned} \tag{25}$$

so that

$$\frac{\partial}{\partial t} n = -\nabla \cdot \mathbf{j}, \qquad \frac{\partial}{\partial t} \mathbf{j} = \nabla n_0 \frac{\delta E[n]}{\delta n} \tag{26}$$

We have recovered, for processes involving the participation of many electrons, the same equations that had been obtained for single electron processes.

4.2.1
Normal Modes

Let us come back to the equations of motion

$$\dot{\phi} = \frac{\delta E[n]}{\delta n}, \qquad \dot{n} = -\nabla \cdot (n_0 \nabla \phi) \tag{27}$$

For small fluctuations, we write

$$\frac{\delta E[n]}{\delta n}(x) = \int dy \kappa(x, y) \delta n(y), \quad \text{with}$$

$$\kappa(x, y) = \frac{\delta^2 E[n]}{\delta n(x) \delta n(y)}\Big|_{n=n_0} \tag{28}$$

Looking for oscillating solutions, the ansatz

$$\begin{aligned}\phi(x, t) &= \cos(\omega_\mu t) \phi_\mu(x), \\ \delta n(x, t) &= \sin(\omega_\mu t) \delta n_\mu(x) \end{aligned} \tag{29}$$

leads to

$$\omega_\mu \delta n_\mu = -\nabla(n_0 \nabla \phi_\mu) \tag{30}$$

$$\omega_\mu \phi_\mu = \kappa \delta n_\mu \tag{31}$$

Observe that $\omega_{\bar{\mu}} = -\omega_\mu$ is also an eigenvalue

$$\omega_{\bar{\mu}} \delta n_{\bar{\mu}} = -\nabla(n_0 \nabla \phi_{\bar{\mu}}) \tag{32}$$

$$\omega_{\bar{\mu}} \phi_{\bar{\mu}} = \kappa \delta n_{\bar{\mu}} \tag{33}$$

being $\phi_{\bar{\mu}} = -\phi_\mu$, $\delta n_{\bar{\mu}} = \delta n_\mu$. The normalization condition

$$\int dx \left(\phi_\alpha(x) \quad \delta n_\alpha(x) \right) \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \times \begin{pmatrix} \phi_\beta(x) \\ \delta n_\beta(x) \end{pmatrix} = \frac{\omega_\alpha}{|\omega_\alpha|} \delta_{\alpha\beta} \tag{34}$$

may be imposed. An arbitrary perturbation may be expanded in the normal modes, that is,

$$\begin{pmatrix} \phi \\ \delta n \end{pmatrix} = \sum_\alpha c_\alpha \begin{pmatrix} \phi_\alpha \\ \delta n_\alpha \end{pmatrix} \tag{35}$$

where

$$c_\alpha = \frac{\omega_\alpha}{|\omega_\alpha|} \int dx \left(\phi_\alpha(x) \quad \delta n_\alpha(x) \right) \times \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} \phi(x) \\ \delta n(x) \end{pmatrix} \tag{36}$$

It may be easily seen that the familiar energy weighted sum rule

$$\sum_{\alpha(\omega_\alpha > 0)} \omega_\alpha c_\alpha^2 = \frac{1}{2} \int dx \, n_0(x) (\nabla \phi)^2 + \frac{1}{2} \int dx \, dy \, \kappa(x, y) \times \delta n(x) \, \delta n(y) \tag{37}$$

is satisfied, which means that the expansion coefficients represent transition amplitudes from the ground state $|\Psi_0\rangle$ to the excited state $|\Psi_\alpha\rangle$,

$$c_\alpha = \left\langle \Psi_\alpha | (Q + P) | \Psi_0 \right\rangle \tag{38}$$

and the absolute values of the frequencies represent excitation energies,

$$|\omega_\alpha| = E_\alpha - E_0 \tag{39}$$

Indeed, for Q and P such that

$$Q = \sum_{j=1}^{N} \phi(x_j),$$

$$\delta n(x) = \mathrm{i}\langle \Psi_0 | [\hat{n}(x), P] | \Psi_0 \rangle \tag{40}$$

we have

$$\begin{aligned}\sum_{\alpha(\omega_\alpha>0)} \omega_\alpha c_\alpha^2 &= \frac{1}{2}\langle \Psi_0 | [Q, [H, Q]] | \Psi_0 \rangle \\ &+ \frac{1}{2}\langle \Psi_0 | [P, [H, P]] | \Psi_0 \rangle \\ &= \frac{1}{2}\langle \Psi_0 | [(P+Q), [H, (P+Q)]] | \Psi_0 \rangle\end{aligned} \tag{41}$$

which is in agreement with

$$\begin{aligned}\sum_\alpha (E_\alpha - E_0) | \langle \Psi_0 | (P+Q) | \Psi_\alpha \rangle |^2 \\ = \frac{1}{2}\langle \Psi_0 | [(P+Q), [H, (P+Q)]] | \Psi_0 \rangle\end{aligned} \tag{42}$$

The main purpose of this exercise has been to state the time-dependent equation of KS with the new interpretation of the currents as transition currents between different states $|\Psi_0\rangle$ and $|\Psi_1\rangle$.

4.2.2
Single Electron Description

In the following, the motion of the nuclei is mainly described by classical trajectories, whereas the density functionals are used to describe the electrons. We shall use atomic units everywhere. We shall denote the densities of electrons, as usual, by n and the corresponding Schrödinger many-particle wave function by $|\Psi(t)\rangle$. As in the standard literature about electronic calculations, we look at the $n(\mathbf{r}, t)$ as evolving from an initial state

$$|\Psi_0\rangle = |\Psi(t_0)\rangle \tag{43}$$

determined by the Schrödinger equation

$$\mathrm{i}\partial\Psi(t)1/\partial t = \hat{H}(t)\Psi(t) \tag{44}$$

$$\hat{H}(t) = \hat{T} + \hat{V}(t) + \hat{U} \tag{45}$$

$$\hat{V}(t) = \sum_{i=1}^{N} v(\mathbf{r}_i, t) \tag{46}$$

$$\hat{T} = \sum_{i=1}^{N} (-1/2)\nabla_i^2 \tag{47}$$

$$\hat{U} = 1/2 \sum_{i,j,i\neq j}^{N} 1/|\mathbf{r}_i - \mathbf{r}_j| \tag{48}$$

so V is an external potential (from nuclei) on electrons and U their mutual repulsion. The last term is by far the most difficult to handle.

It is obviously not small compared to the other terms. The method suggested in Bang and Hansteen (2002), however, facilitates the treatment of just that term.

We shall assume that a local single-particle potential, $v_s[n](\mathbf{r}, t)$, exists, which reproduces the time-dependent density

$$n(\mathbf{r}, t) = \sum_{j=1}^{N} |\phi_j(\mathbf{r}, t)|^2 \tag{49}$$

with orbitals satisfying the KS (or Schrödinger) equation

$$(\mathrm{i}\partial/\partial t + \nabla^2/2 - v_s[n](\mathbf{r}, t))\phi_j(\mathbf{r}, t) = 0 \tag{50}$$

Generally,

$$\begin{aligned}v_s[n](\mathbf{r}, t) &= v(\mathbf{r}, t) \\ &+ \int d^3r' n(\mathbf{r}', t)/|\mathbf{r} - \mathbf{r}'| + v_{\mathrm{xc}}[n](\mathbf{r}, t)\end{aligned} \tag{51}$$

where Eq. (49) *defines* the time-dependent xc potential. A general matrix element of $v_s[n]$, corresponding to a transition from single-particle state i to single-particle state j

$$\langle \phi_j | v_s[n] | \phi_i \rangle \tag{52}$$

can be viewed as a sum over the single-particle constituents (j') of n in the *second* term of Eq. (10)

$$\begin{aligned} v_s[n] &= \int d^3r' n(\mathbf{r}', t)/|\mathbf{r}-\mathbf{r}'| \\ &= \int d^3r' \sum_{j'} |\phi_j'|^2/|\mathbf{r}-\mathbf{r}'| \end{aligned} \tag{53}$$

which can again be considered as the trace of the more general matrix

$$\mathrm{trace}[v_s[n]_{i',j'}] = \mathrm{trace} \int d^3r' \phi_{i'}^* \phi_{j'}/|\mathbf{r}-\mathbf{r}'| \tag{54}$$

Now, as in Bang and Hansteen (2002), the idea is to use the Schrödinger equation, satisfied by all ϕ_m, and then derive from that the continuity equation for single-particle electron densities

$$\partial n(\mathbf{r}, t)/\partial t = -\nabla \mathbf{j}(\mathbf{r}, t) \tag{55}$$

to introduce, instead of the electron transition densities $n_{i,j}$, the corresponding *transition current densities*. In Gross *et al.* (1996) currents are also introduced, but in a more formal way, which does not demonstrate the full calculational advantage of this particular step.

The main point is now to use the time-dependent Schrödinger equation and, as the consequence of it, the continuity equation to eliminate the single-particle densities in favor of similar *longitudinal* single-particle currents

$$\frac{\partial \rho_{ki}}{\partial t} = \mathrm{i}\frac{div_r \mathbf{j}_{ki}}{E_k - E_i}\hbar \tag{56}$$

Since Eq. (55) can be separated in a time- and a space-dependent partial differential equation, a similar elimination can be made here. The single-particle energies E_i, and so on, are replaced here by the separation constants e_i, and so on, so also the denominators $E_{ki}/\hbar^2$ should be replaced by $e_{ki} = e_k - e_i$. Remember $\mathbf{r}_- = |\mathbf{r} - \mathbf{r}'|$.

We may, as explained in Appendix 4.B and Bang and Hansteen (2002), introduce the *longitudinal* currents

$$\mathbf{j}^L(\mathbf{r}) = -\nabla_r \int dr'^3 div_{r'} \mathbf{j}(\mathbf{r}')/|4\pi \mathbf{r}_-| \tag{57}$$

and by a partial integration, we get the general Coulomb matrix element, connecting the transition densities $n_{ki}(\mathbf{r})$, $n_{jh}(\mathbf{r}')$:

$$I_{ki;jh} = \int d^3r (\mathbf{j}_{ki}^L \cdot \mathbf{j}_{jh}^L) 4\pi / e_{ki} e_{jh} \tag{58}$$

and the similar equation for the transverse component $\mathbf{j}_{ki}^T$. Here, again the longitudinal and transverse currents in a spherical system take simple forms, which can be expressed by means of vector spherical harmonics. A longitudinal field can be written as

$$\begin{aligned} \mathbf{L}_{J,M} &= \nabla([\Phi^J]^{\mathrm{long}} Y_{J,M}) \\ &= -\sqrt{(J+1)/(2J+1)} \\ &\quad \times (d/dr - (J+0)/r)[\Phi^J]^{\mathrm{long}} Y_{J,J+1,M} \\ &\quad + \sqrt{(J+0)/(2J+1)} \\ &\quad \times (d/dr + (J+1)/r)[\Phi^J]^{\mathrm{long}} Y_{J,J-1,M} \end{aligned} \tag{59}$$

Analogously, a transverse field can be written as

$$\begin{aligned}\mathbf{T}_{J,M} &= \sqrt{(J+0)/(2J+1)}\\ &\quad\times \big(d/dr - (J+0)/r\big)\\ &\quad\times \big[\Phi^J\big]^{\mathrm{tran}}\, Y_{J,J+1,M}\\ &\quad+ \sqrt{(J+1)/(2J+1)}\\ &\quad\times \big(d/dr - (J+1)/r\big)\\ &\quad\times \big[\Phi^J\big]^{\mathrm{tran}}\, Y_{J,J-1,M} \end{aligned} \tag{60}$$

This is not the only transverse field; any field where the vector spherical harmonics are of the type

$$Y_{J,J,M} \tag{61}$$

is also transverse. But the total Fermion vector density with quantum numbers $[J, l, M]$, where l is different from J, may be written as $\mathbf{A}_{J,l,M} = \mathbf{L}_{J,l,M} + \mathbf{T}_{J,l,M}$. The occurrence of e_{ki}, and so on, in the denominators seems somewhat inconvenient since whenever $e_k = e_i$, these denominators become zero. The corresponding numerators also become zero, however. The construction of a general transition current, containing both longitudinal and transverse components, from the single-particle electron wave functions in a spherical field, was demonstrated in Bang and Hansteen (2002), Appendix 4.A. The vector spherical harmonics, which are eigenfunctions of an angular momentum **J** with magnetic components **M**, given by addition of an orbital angular momentum **L** and a unit angular momentum **S**, eigenvectors **e**, are expressed as

$$\mathbf{Y}_{J,L,M} = \sum_{m,q} Y_{L,m}(\Omega)\, \mathbf{e}_q(Lm1q|JM) \tag{62}$$

A gradient of a single-particle wave function can be written as

$$\begin{aligned}\nabla(\phi_n Y_{\nu,m_n}) &= \phi_{\nu+} Y_{\nu,\nu+1,m_n}\\ &\quad+ \phi_{\nu-} Y_{\nu,\nu-1,m_n}\end{aligned} \tag{63}$$

where we for the moment introduce the convention that a state with quantum number n has orbital angular momentum quantum number named by the corresponding Greek letter ν

$$\begin{aligned}\phi_{\nu+} &= -\sqrt{((\nu+1)/(2\nu+1))}\\ &\quad\times (d/dr - (\nu+0)/r)\phi_n\end{aligned} \tag{64}$$

$$\begin{aligned}\phi_{\nu-} &= +\sqrt{((\nu+0)/(2\nu+1))}\\ &\quad\times (d/dr + (\nu+1)/r)\phi_n\end{aligned} \tag{65}$$

The terms in the current contain the factors

$$Y^*_{\kappa,m_k}\mathbf{Y}_{\iota,\lambda,m_i} = \sum_{JlM} \mathbf{Y}_{J,l,M} X_{JlM} \tag{66}$$

where the factor X is constructed from 6J symbols, which are (for typographical reasons) replaced here and in Bang and Hansteen (2002) by the equivalent U symbols of Jahn.

$$\begin{aligned}&X_{JlM} = \sqrt{(2\kappa+1)(2\lambda+1)/4\pi(2l+1)}(-)^{m_k}\\ &U\big(1,\lambda,J,\kappa;\iota,l\big)\big(\kappa,-m_k,\iota,m_i|J,M\big)\\ &\quad\times\big(\kappa,0,\lambda,0|l,0\big)\end{aligned} \tag{67}$$

The spherical harmonics together with radial functions, $\phi_n(r)$, constitute the single-particle wave functions. To construct the single-particle transition currents, we need a general expression for the gradient of a single-particle wave function (Eqs (63)–(65)) together with the above combination formulas (Eq. (66)). From Eqs (66) and (67) above, we get the general expressions for longitudinal and transverse transition current densities

$$F^L_{J+}\mathbf{Y}_{J,J+1,M} + F^L_{J-}\mathbf{Y}_{J,J-1,M} \tag{68}$$

$$F^T_{J+}\mathbf{Y}_{J,J+1,M} + F^T_{J-}\mathbf{Y}_{J,J-1,M} \tag{69}$$

The sum of all the four last terms should be equivalent to the transition current densities calculated from Eqs (67) and (68), and since the vector spherical harmonics are orthogonal for different values of all three quantum numbers, the same equivalence must be true for the coefficients F. So, from these equations, we get the desired longitudinal current components.

4.2.3
Electron–Nuclei Description

In this chapter as well as in Gross *et al.* (1996), a possible motion of nuclei is also included, and hence one gets a set of coupled equations for electrons and nuclei:

$$\mathrm{i}\frac{\partial\phi_j}{\partial t} = \left(-\frac{1}{2}\nabla_r^2 + v_s[n, n_B](\mathbf{r}, t)\right) \times \phi_j(\mathbf{r}, t), \quad [j = 1, \ldots, N] \tag{70}$$

$$\mathrm{i}\frac{\partial\psi_{A\alpha}}{\partial t} = \left(-\frac{1}{2M_A}\nabla_R^2 + V_s^A[n, n_B](\mathbf{R}, t)\right) \times \psi_{A\alpha}(\mathbf{R}, t) \tag{71}$$

where nucleon α is associated with nucleus A, so that the nuclear densities read

$$n_A(\mathbf{R}, t) = \sum_{\alpha=1}^{N_A} n_{A,\alpha}(\mathbf{R}, t) = \sum |\psi_{A\alpha}(\mathbf{R}, t)|^2 \tag{72}$$

and electron densities

$$n(\mathbf{r}, t) = \sum_{j=1}^{N} |\phi_j(\mathbf{r}, t)|^2 \tag{73}$$

Correspondingly, we have the KS potentials

$$v_s[n, n_B](\mathbf{r}, t) = v_{\text{ext}}(\mathbf{r}, t) + \int d^3r'\frac{n(0\mathbf{r}', t)}{|\mathbf{r} - \mathbf{r}'|} - \sum_{B=1}^{K}\int d^3R\frac{Z_B n_B(\mathbf{R}, t)}{|\mathbf{r} - \mathbf{R}|} + v_{\text{xc}}[n, n_B](\mathbf{r}, t) \tag{74}$$

$$V_s^A[n, n_B](\mathbf{R}, t) = V_{\text{ext}}^A(\mathbf{R}, t) - Z_A\int d^3r' \times \frac{n(\mathbf{r}', t)}{|\mathbf{R} - \mathbf{r}'|} + Z_A\sum_{B=1}^{K}\int d^3R'\frac{Z_B n_B(\mathbf{r}', t)}{|\mathbf{R} - \mathbf{R}'|} + V_{\text{xc}}^A[n, n_B](\mathbf{R}, t) \tag{75}$$

corresponding to Eq. (54).

The important case of $e_i = e_k$ deserves special attention. Here, $div\mathbf{j}_{ki}/e_{ki}$ can be considered a limiting case of $e_k = e_i + d$ for $d \to 0$:

$$(\nabla(\psi_k^*\nabla\psi_i - \psi_i\nabla\psi_k^*))/e_{ki} \tag{76}$$

$$= ((\Delta\psi_i)\psi_k^* - (\Delta\psi_k^*)\psi_i)/e_{ki} \tag{77}$$

$$= bd\psi_i\psi_k^*/e_{ki} = b|\psi_i(r)|^2 \tag{78}$$

The last formulation assumes that we further have $\psi_i = \psi_k$, as in the nondegenerate case of single-particle n, again looking apart from spin. Here, b in atomic units is 1.

Gross *et al.* (1996) proved that different currents

$$\mathbf{j} = \langle\psi(t)|\hat{j}|\psi(t)\rangle \tag{79}$$

and

$$\mathbf{j}' = \left\langle\psi(t)'|\hat{j}|\psi(t)'\right\rangle \tag{80}$$

correspond to different external potentials v, v', and therefore to different solutions of KS equations.

Once the external potentials are fixed, all other matrix elements of one- and two-body operators between different states of the system determined by $\hat{H}$ are also given.

Although it is obvious that a completely quantum mechanical treatment of the electron motion is superior to a classical one, the motion of the nuclei seems fit for use of classical or semiclassical methods, as also realized in Gross *et al.* (1996). From Ehrenfests theorem applied to the nuclear KS equation, the classical trajectory is given as

$$\mathbf{R}^{\text{class}}_{A\alpha} = \left\langle \psi_{A\alpha}(t) | \hat{\mathbf{R}} | \psi_{A\alpha}(t) \right\rangle \tag{81}$$

$$= \int d^3R\mathbf{R}n_{A\alpha}(\mathbf{R}, t) \tag{82}$$

We see that

$$M_A d^2\mathbf{R}^{\text{class}}_{A\alpha}/dt^2(t) = \mathbf{F}_{A\alpha}(t) \tag{83}$$

with

$$\mathbf{F}_{A\alpha}(t) = -\left\langle \psi_{A\alpha}(t) | \nabla_R V^A_s | \psi_{A\alpha}(t) \right\rangle \tag{84}$$

In some cases, the nuclear densities may be rather narrowly peaked distributions around a classical trajectory. Such distributions may, for example, be forced upon a system by introducing appropriate screens in an experiment. The practical difficulties of such a procedure should not prevent us from using it in a theoretical description, since the spreading of wave packets is in many cases shown to be *relatively* small (as exemplified by scattering of slow nuclei in Coulomb fields). Under such circumstances, the equations of motions for the nuclei reduce to

$$M_A \frac{d^2}{dt^2}\mathbf{R}^{\text{class}}_{A\alpha}(t) = -\nabla\left[V^A_{\text{ext}}(\mathbf{R}^{\text{class}}_{A\alpha}, t) - \int d^3r \frac{Z_A n(\mathbf{r}, t)}{|\mathbf{R}^{\text{class}}_{A\alpha} - \mathbf{r}|} + \sum_{B=1}^{K}\sum_{\beta=1}^{N_B} \frac{Z_A Z_B}{|\mathbf{R}^{\text{class}}_{A\alpha} - \mathbf{R}^{\text{class}}_{B\beta}|}\right] \tag{85}$$

and the electronic KS equations simplify to

$$\mathrm{i}\frac{\partial \phi_j(\mathbf{r}, t)}{\partial t} = \left[-\nabla^2/2 + v_{\text{ext}}(\mathbf{r}, t) + \int d^3r' \frac{n(\mathbf{r}', t)}{|\mathbf{r} - \mathbf{r}'|} - \sum_{B=1}^{K}\sum_{\beta=1}^{N_B} \times \frac{Z_B}{|\mathbf{R}^{\text{class}}_{\mathrm{B}\beta}(t) - \mathbf{r}|} + v_{\text{xc}}\left[n, \mathbf{R}^{\text{class}}_{\mathrm{B}\beta}(t)\right](\mathbf{r}, \mathbf{t})\right]\phi_j(\mathbf{r}, t) \tag{86}$$

Equations (81) and (82) are evidently coupled, and they must be simultaneously solved, thus achieving the trajectory.

Such unique trajectories are, however, not the only possibility. In potentials that give rise to classical crossing points or branching points, the quantum mechanical wave packets may be split into two or more, centered around different trajectories, even giving rise to interference effects. In such cases, the classical treatment becomes insufficient, and a solution of the original Eqs 70) and 71 cannot be avoided, at least in the neighborhood of classical crossing points or branching points. Let us, however, first return to the simple case of one classical trajectory.

The interaction between nuclei and electrons is given here by a matrix of four indices (see Appendix 4.B and Bang and Hansteen (2002) Eqs (7)−(11) $[I_C]_{ki,jh}$ of which the first two (ki) correspond to the initial and final (external, center of mass (CM)) states of the nuclei, the last two (jh) to the initial and final states of electrons.

$$[I_C]_{ki,jh} C \int d^3r \left(\mathbf{j}(\mathbf{r})^{\mathrm{long}}_{ki} / e_{ki} \mathbf{j}(\mathbf{r})^{\mathrm{long}}_{jh} / e_{jh} \right) \tag{87}$$

The factor, C, in front of the integral is a scaling factor due to the transition from the nuclear coordinates to electronic ones used in the partial integration of (see Appendix 4.B and Bang and Hansteen (2002) Eq. (7))−(11). Each nucleus obviously contributes a current component that has a direction antiparallel to the momentum transfer in the transition current $\mathbf{j}_{jh}$ of the electron considered. The nuclear current component is contained in a sphere with radius approximately $1/M$ in atomic units. The total contribution of nuclei of one sort to the force on one electron undergoing a transition between states j, h is just

$$\sum_{B=1}^{K} \sum_{\beta=1}^{N_B} I_C \tag{88}$$

We now return to the case of trajectories with crossing points or branching points. We shall try to solve the coupled equations (Eqs (70) and (71)) with the boundary condition that at the time $t_1 < t_c$ the solution for the electrons is ϕ_a. Here, t_c is the time of the collision. For $t_2 > t_c$, the electronic solution is $a\phi_a + b\phi_b$ with $|a|^2 + |b|^2{=}1$. We see that $|a/b| = |\psi_{A\alpha}|/|\psi_{B\beta}|$, when $t_1 \ll t_2$. We have sketched here how an electron transfer may be described. It can either be a transfer between two atoms in one molecule or between atoms in different molecules. In the first case, we may again directly introduce the classical approximation for the motion of the center of mass of the nuclei. In the second case, the coupled equations must be used in the neighborhood of crossing points and branching points.

To get the complete description of wave functions and densities of *electrons*, we must further add the remaining terms of Eq. (81) to the Hamiltonian. It should be noted, though, that the terms denoted v_{xc} have been treated particularly in Bang and Hansteen (2002), Chapter 5. We see that the attraction of nuclei of one sort, lying on a single curve, can be simulated by a classical current contained in a thin (order of magnitude of width $1/M$) conductor on the same curve interacting with the electron transition current density with a contact interaction. The method can be extended to other nuclei, not lying on the curve, by using the methods of crossing and branching points, mentioned earlier. It seems that these methods are particularly fit for long, chain-like molecules. It is evident that the same longitudinal electron transition current densities are met in the nucleus–electron interaction and in the electron–electron interaction. These currents or rather their spherical components should therefore be stored, so much more as each transition current density can occur in several matrix elements.

4.3
Relativistic Electrons

Another interesting problem is connected with relativistic effects. The kinetic energies of electrons in atoms and molecules are only in the neighborhood of the very heaviest nuclei of such an order of magnitude that relativistic effects come into play in a direct way. However, magnetic interactions can always be considered as relativistic effects and a proper treatment as that may be, not only consistent but also the simplest way, as shown later.

The electric current density in the Dirac theory of relativistic electrons is given as the three-vector part of a four-vector:

$$s_{\nu=1,2,3,4} = \mathrm{i}ec\bar{\boldsymbol{\Psi}}\gamma_\nu\boldsymbol{\Psi} \tag{89}$$

$$s_{k=1,2,3} = \mathrm{j}_k; \ldots s_4 = \mathrm{i}c\rho \tag{90}$$

The 4-vector s_ν can be decomposed

$$s_\nu = s_\nu^C + s_\nu^P \tag{91}$$

so that the space part of s^C, the *conduction current* is of the same form as the nonrelativistic expression for j_k. The remaining part is the *polarization current* s_k^P. The Dirac State vector is here

$$\boldsymbol{\Psi} = \sum_\nu \psi_\nu \mathbf{e}_\nu \tag{92}$$

and the conjugate

$$\bar{\boldsymbol{\Psi}} = \boldsymbol{\Psi}^\dagger\alpha_0 = \sum_\nu \bar{\psi}_\nu \mathbf{e}_\nu^{\mathrm{T}} \tag{93}$$

where $\mathbf{e}_\nu^{\mathrm{T}}$ stands for the transposed of $\mathbf{e}_\nu$. Here, the ψ are functions of x, y, z, t and the $\mathbf{e}$ are orthogonal unit vectors in spin space. The Dirac equation is now

$$\begin{aligned}&\left[\boldsymbol{\alpha}_0 mc+\sum_k \boldsymbol{\alpha}_k\left(\frac{\hbar}{\mathrm{i}}\frac{\partial}{\partial x_k}-\frac{e}{c}A_k\right)+e\phi\right]\boldsymbol{\Psi}\\ &= \left[\boldsymbol{\alpha}_0 mc\boldsymbol{\Psi}+\boldsymbol{\alpha}\left(\frac{\hbar}{\mathrm{i}}\nabla\boldsymbol{\Psi}-\frac{e}{c}\mathbf{A}\boldsymbol{\Psi}\right)+e\phi\boldsymbol{\Psi}\right]\\ &= -\frac{\hbar}{\mathrm{i}c}\frac{\partial\boldsymbol{\Psi}}{\partial t}\end{aligned} \tag{94}$$

Here, $\boldsymbol{\alpha}$ is a vector with components α_k and $\alpha_0 = \rho_0$, the familiar Dirac matrices. The continuity equation in this relativistic case becomes

$$\frac{\partial(\boldsymbol{\Psi}^\dagger\boldsymbol{\Psi})}{\partial t} = -c\; div(\boldsymbol{\Psi}^\dagger\alpha\boldsymbol{\Psi}) \tag{95}$$

Any field in three dimensions may be split in a longitudinal and a transverse part

$$\mathbf{j} = \mathbf{j}^{\mathrm{long}} + \mathbf{j}^{\mathrm{tran}} \tag{96}$$

$$\begin{aligned}\mathbf{j}^{\mathrm{long}} &= -\nabla_r \int d^3r' \frac{div_{r'}\mathbf{j}(r')}{4\pi|\mathbf{r}-\mathbf{r}'|};\\ \mathbf{j}^{\mathrm{tran}} &= -\mathrm{curl}_r \int d^3r' \frac{\mathrm{curl}_{r'}\mathbf{j}(r')}{4\pi|\mathbf{r}-\mathbf{r}'|}\end{aligned} \tag{97}$$

Let the transition current field be given by its relativistic form in spherical coordinates

$$\mathbf{j}_{ki}^1 = iec\bar{\boldsymbol{\Psi}}_k\boldsymbol{\gamma}\boldsymbol{\Psi}_i \tag{98}$$

with the spinors

$$\boldsymbol{\Psi}_{i,J_i,l_i,M_i} = \mathcal{F}(r,t)_i\mathcal{Y}_{lm}\chi_\mu(lm1/2\mu|l1/2JM) \tag{99}$$

In the presence of a magnetic field, the one-electron current density takes the form

$$\begin{aligned}\mathbf{j}_{ki}^{\mathrm{A}} = \frac{\hbar}{2mi}\Big(&\boldsymbol{\Psi}_k^*\boldsymbol{\nabla}\boldsymbol{\Psi}_i - \boldsymbol{\Psi}_i\boldsymbol{\nabla}\boldsymbol{\Psi}_k^*\\ &-\frac{2ie}{c\hbar}\mathbf{A}\boldsymbol{\Psi}_k^*\boldsymbol{\Psi}_\mathrm{i}\Big)\end{aligned} \tag{100}$$

or in spherical form

$$\mathbf{j}^A = C_1\mathbf{j}_{JlM}^1 - C_2(\mathbf{A}\rho)_{JlM} \tag{101}$$

where the Cs are given in Eqs (71)–(73) and $(\mathbf{A}\rho)_{JlM}$ is given by the definition of vector spherical harmonics in the expression

$$\mathbf{A}\rho = \mathbf{A}\sum_{mq} Y_{lm}\mathbf{e}_q(lm1q|l1JM) \tag{102}$$

Remember that $\mathbf{A}$ is a vector and ρ a scalar. The *longitudinal* part of these vectors is now found in the same way as in Bang and Hansteen (2002). In order to treat the magnetic interactions between electrons and between nuclei as well as between nuclei and electrons, we shall look at the transverse transition current densities. At the same time we shall introduce a new form of these current densities, appropriate for the interactions with magnetic fields:

$$\mathbf{s}_{ki} = \mathbf{j}_{ki} - \frac{e^2}{c}\,\mathbf{A}\boldsymbol{\Psi}_k^*\boldsymbol{\Psi}_i \qquad (103)$$

$$\mathbf{s}^{\mathrm{T}} = \mathrm{curl}_r \int d^3\mathbf{r}'\,\frac{\mathrm{curl}_{r'}(\mathbf{s}(\mathbf{r}') - \frac{e^2}{c}\,\mathbf{A}\rho(\mathbf{r}'))}{4\pi\,|\mathbf{r}-\mathbf{r}'|} \qquad (104)$$

with

$$\rho(\mathbf{r}') = \Psi_k^*(\mathbf{r}')\Psi_i(\mathbf{r}') \qquad (105)$$

The new expression for the current density gives the same continuity expression as the previous one. The curl $\mathbf{A} = \mathbf{H}$ gives the connection to the magnetic field (which could originate from other electrons or nuclei, static or in transitions in general $(j{-}h)$). The magnetic interaction energy $[ki, jh]$ can again be written by means of the integral of a scalar product of two transition densities, $\mathbf{j}_{ki}^{T}$ and $\mathbf{j}_{jl}^{T}$. Note, however, that the two proportionality constants in the electric and magnetic energies, expressed by means of currents, are different. To show the effect of the method of giving the matrix elements by means of currents, we shall start from the final result and work backward

$$I_M = \int d^3r(\mathbf{j}(\mathbf{r})_{ki}^{\mathrm{T}}\,\mathbf{j}(\mathbf{r})_{jh}^{\mathrm{T}})C_{ki,jh} \qquad (106)$$

where

$$\mathbf{j}(\mathbf{r})^{\mathrm{T}} = \mathrm{curl}_r \int d^3\mathbf{r}'\,\frac{\mathrm{curl}_{\mathbf{r}'}\mathbf{j}(\mathbf{r}')}{4\pi\,|\mathbf{r}-\mathbf{r}'|} \qquad (107)$$

(Note, however, that the constant C in the magnetic matrix elements is different from the corresponding constant in the electric matrix element).

Note also that the current in the magnetic matrix element must include the electromagnetic potential $\mathbf{A}$, and that the transverse current densities have the same form as the source terms of *electric* multipole radiation (and vice versa with magnetic multipole radiation).

The occurrence of curl$\mathbf{j}$ in Eq. (107) and elsewhere may seem inconvenient, since this expression is not part of the common formulas, derived from Maxwell's or Schrödingers equations. Introducing

$$\mathbf{j}^{\mathrm{T}} = \mathbf{j} - \mathbf{j}^{\mathrm{L}} \qquad (108)$$

this formal problem is avoided.

4.4
The General Description for the Electronic Evolution Equations

In the earlier chapters, we introduced the transition currents for calculation of electric and magnetic matrix elements. The advantages of introducing that, as suggested here, are several:

First, this procedure, or these procedures, are known to lead to similar simplifications compared to Hartree–Fock methods as those of density methods Gross *et al.* (1996). Secondly, the currents give a simpler connection to dynamic problems, than do static densities. Thirdly, we have just shown that even magnetic interactions can, by means of the currents, be expressed in a particularly simple way. And fourthly, as already shown in Bang and Hansteen (2002), special methods for calculations of integrations in matrix elements permit us to avoid unwieldy, sometimes even singular, integrals.

As a fifth point, it should be mentioned that the classification used here, of dividing vector functions in longitudinal and transverse vector functions, is a very natural one, when thinking of local, as distinguished from global, classifications.

Further simplifications may be obtained by using a special representation for the wave functions, and consequently also for the currents. We shall here, neglecting spin, use the basis of wave functions of electrons around a point nucleus of infinite mass, and charge eZ, factorizing the wave function in the usual way:

$$\phi = 1/r\chi_l(r)Y_{lm}(\theta, \phi) \tag{109}$$

$$\chi_l'' + (-\gamma^2 + 2\gamma\kappa/r - l(l+1)/r^2)\chi_l = 0 \tag{110}$$

$$2mE/\hbar^2 = -\gamma^2 \tag{111}$$

$$\kappa = Ze^2m/(\hbar^2\gamma) \tag{112}$$

and introduce a dimensionless radial variable

$$z = r/\alpha_0 = r\gamma = rZ/n \tag{113}$$

Now according to Appendix 4.B and Bang and Hansteen (2002), the transition current density in this representation has matrix elements given by vector spherical harmonics, cf. Eqs (59)–(69).

$$\begin{aligned}[\mathbf{j}_{ki}]_{JlM} &= [\phi(r)_k Y^*_{l_k m_k} \nabla\phi(r)_i Y_{l_i m_i}]_{JlM} \\ &\quad - [\phi(r) - \mathrm{i} Y_{l_i m_i} \nabla\phi(r)_k Y^*_{l_k m_k}]_{JlM}\end{aligned} \tag{114}$$

The radial part of $\mathbf{j}_{ki}$ can be written as

$$F_{\alpha,J,l,M} = F^{\alpha} - F^{\alpha'} \tag{115}$$

Here, α' means that in the second term of $\mathbf{j}$ the roles of i, k are interchanged, although ϕ_k still occurs with complex conjugation cf. Bang and Hansteen (2002).

So equating the coefficients of $\mathbf{Y}_{J,l,M}$ in the transition current densities

$$\mathbf{j} = \sum_{J,l=J\pm1,M} F_{\alpha,J,l}\mathbf{Y}_{J,l,M} \tag{116}$$

and those in $\mathbf{L}_{JM} + \mathbf{T}_{JM}$, we get

$$(d/dr - J/r)u_J = F_{\alpha,J,J+1} \tag{117}$$

$$(d/dr + (J+1)/r)v_J = F_{\alpha,J,J-1} \tag{118}$$

where

$$\begin{aligned}u(r)_J &= \sqrt{J/(2J+1)}\Phi_J^T \\ &\quad - \sqrt{(J+1)/(2J+1)}\Phi_J^L\end{aligned} \tag{119}$$

$$\begin{aligned}v(r)_J &= \sqrt{J/(2J+1)}\Phi_J^L \\ &\quad + \sqrt{(J+1)/(2J+1)}\Phi_J^T\end{aligned} \tag{120}$$

The differential equations (Eqs 117 and 118) are to be solved to get $u(r)$, $v(r)$. Although this is not difficult for small molecules, in the case of larger molecules, it could be time consuming. An alternative method could be to expand the $F_{\alpha,J,l}$ on functions that lead to algebraic solutions of Eqs (117) and (118), as would be the case if the transition currents were currents in atoms with a fixed nucleus of point charge. Regardless of how Eqs (117) and (118) are solved, the next step should be to invert the equations to get the $\mathbf{\Phi}_J^L$, $\mathbf{\Phi}_J^T$ from which the respective electric, and magnetic electron, interactions are constructed:

$$\Phi_J^L = v_J\sqrt{J/(2J+1)} - u_J\sqrt{(J+1)/(2J+1)} \tag{121}$$

$$\Phi_J^T = u_J\sqrt{J/(2J+1)} + v_J\sqrt{(J+1)/(2J+1)} \tag{122}$$

These equations constitute the main framework for solving the evolution of the electronic structure in molecules. The equations are in time, meaning that the parameter, or the argument, of the two electron evolution equations can be considered as any variable since the potentials, and therefore also the Fs, are time dependent. The time dependence is basically through the nuclear dynamics, see Section 4.2.3. Ehrenfest theorem of the time evolution of the wave packet can also be applied in this case guaranteeing that the time evolution of $u(r, t)$, $v(r, t)$ will have an extra time parameter in the exponent. Such a parameter, however, disappears in the calculation of the density and the density of the currents. Overall, we build the formalism for the transition currents between different orbitals in time. Thus, we can write

$$u(r, t)_J = \sqrt{J/(2J+1)}\Phi(r, t)_J^T - \sqrt{(J+1)/(2J+1)}\Phi_J^L(r, t) \tag{123}$$

$$v(r, t)_J = \sqrt{J/(2J+1)}\Phi(r, t)_J^L + \sqrt{(J+1)/(2J+1)}\Phi_J^T(r, t) \tag{124}$$

and similarly

$$\Phi(r, t)_J^L = v_J\sqrt{J/(2J+1)} - u_J\sqrt{(J+1)/(2J+1)} \tag{125}$$

$$\Phi(r, t)_J^T = u_J\sqrt{J/(2J+1)} + v_J\sqrt{(J+1)/(2J+1)} \tag{126}$$

Equations (117) and (118), and the ones just mentioned, are of the linear type, which are described and, generally, solved in the comprehensive book by Kamke (1983). With the notation given in Kamke (1983), both the equations can be written as

$$dy/dx + f(x)y = g_y(x) \tag{127}$$

with the solution

$$y = \exp(-F)[a + \int_b^x g(x')\exp(F)dx'] \tag{128}$$

Here,

$$F(x)^u = F(r) = -\int_b^r (J+1)/r'dr' = r^{-J}/b^{-J} \tag{129}$$

whereas in the next equation

$$F(x)^v = \int_b^r (J)/r'dr' = r^{-J+1}/b^{-J+1} \tag{130}$$

The lower limit of the two integrals is close to zero. Next, we will write

$$g_u(r) = \exp(-yr)G_u(r) \tag{131}$$

$$g_v(r) = \exp(-yr)G_v(r) \tag{132}$$

and we shall suppose that the G-functions can be Taylor expanded around $r = 0$. Hence,

$$G_u = \sum_{n=0}^{N} A_n^u r^n; \quad G_v = \sum_{n=0}^{N} A_n^v r^n \tag{133}$$

The equations for $u_J(r)$, $v_J(r)$ have the solution

$$v_J = r^{-(J+1)}\int_0^r dr' r'^{(J+1)} F^v_{\alpha,J,J-1}(r') \tag{134}$$

and correspondingly for u_J, but with $A = -J$, which we may solve in a similar way, assuming that J is different from 1. (The case, $J = 1$, can be dealt with by a limiting procedure, $J \to 1$). Altogether, we get for the first term, for example, in the Taylor expansion of F

$$A_1^{\text{Taylor}} = F_0\big(r^J r^{-(J+1)} - b^J b^{-(J+1)}\big); \quad \text{where} \quad b \to 0 \tag{135}$$

We see that the electron–electron interaction strength corresponding to the two transitions

$$\alpha = [i, k] \tag{136}$$

and

$$\beta = [j, h] \tag{137}$$

is given directly by the scalar product of the corresponding transition current densities, integrated over all space. Antisymmetry of the wave functions simply means that the Pauli exclusion principle should be implemented on each pair of states. In Bang and Hansteen (2002), Eq. (7), another way of writing j^L_{ki} was suggested:

$$j(r)^L_{ki} = \int dr'^3 \nabla_{r'} (\rho(r)_{ki} \mathrm{i} E_{ki}/(4\pi \mid r_- \mid) \tag{138}$$

We see that with this formulation, inconvenient energy denominators E_{ki} are removed.

The transition matrix element from one orbital Ψ_0 to another Ψ_1 is described by

$$\left\langle \Psi_0 \mid \hat{\mathbf{j}}(r) \mid \Psi_1 \right\rangle \tag{139}$$

where the transition current $\mathbf{j}$ is given by Eq. (116). Note, however, that the definition (24), involving the explicit dependence on $\mathbf{r}$ is familiar in nuclear physics applications and may also lead to useful information. Let us consider a state vector $|\Psi(t)\rangle$ of some molecule, containing an admixture of excited states, $|\Psi(t)\rangle = e^{-\mathrm{i}E_0 t}|\Psi_0\rangle + c_1 e^{-\mathrm{i}E_1 t}|\Psi_1\rangle$, so that it is nonstationary. The current $\mathbf{j}(r, t) = \langle \Psi(t)|\hat{\mathbf{j}}(\mathbf{r})|\Psi(t)\rangle$ is clearly time dependent. Its Fourier components in time are given by the matrix elements of $\hat{\mathbf{j}}(\mathbf{r})$. Indeed, $\mathbf{j}(\mathbf{r}, t) = c_1\langle \Psi_0|\hat{\mathbf{j}}(\mathbf{r})|\Psi_1\rangle e^{-\mathrm{i}(E_1-E_0)t} + c_1^*\langle \Psi_1|\hat{\mathbf{j}}(\mathbf{r})|\Psi_0\rangle e^{\mathrm{i}(E_1-E_0)t}$, since $\langle \Psi_0|\hat{\mathbf{j}}(\mathbf{r})|\Psi_0\rangle = 0$. We have assumed $|c_1| \ll 1$, so that we have neglected quadratic terms in c_1. The excited states determine the current through the matrix elements $\langle \Psi_0|\hat{\mathbf{j}}(\mathbf{r})|\Psi_1\rangle$, which, therefore, are called transition currents.

4.5
Multielectronic Interaction and Collective Phenomena

Up to now, we have basically been treating the electronic media as single electronic equations of motion. If we should extend the single-particle description to a many-body framework, we should expect to have to deal with collective phenomena as far down as to collective coordinates.

4.5.1
Collective Coordinates and Plasmons

In this respect, classical dynamics may prove to be a useful tool for the description of collective phenomena involving a very large number of electrons, provided the Pauli Principle is properly taken into account, as explained in the sequel. As an example of the approach we have in mind, we consider a two-components system, namely, a large number of positive ions and a large number of electrons in interaction, in appropriate amounts to ensure charge neutrality. For each species, the Vlasov equation

$$\frac{\partial f}{\partial t} + \{h, f\} = 0 \tag{140}$$

describes the respective dynamics. Here, $f = f(\mathbf{r}, \mathbf{p}, t)$ denotes the familiar distribution function $h = h(\mathbf{r}, \mathbf{p}, t)$ – the single-particle hamiltonian – and $\{h, f\} = \sum_{i=1}^{3} \left(\frac{\partial h}{\partial x_i}\frac{\partial f}{\partial p_i} - \frac{\partial f}{\partial p_i}\frac{\partial h}{\partial x_i}\right)$ – the familiar Poisson bracket. Everything is classical, except that f is supposed to assume only two possible values, 0 and 1, according to the Pauli Principle requirements. It is easy to see that if this property is imposed at time $t = 0$, the dynamics will take care to preserve it forever.

We write $f = f_0 + \delta f$, $h = h_0 + \delta h$, where f_0 and h_0 are, respectively, the equilibrium distribution function and hamiltonian (so that $\{h_0, f_0\} = 0$) and δfandδh are the corresponding fluctuating parts. We denote by S the generator of the fluctuations, that is, $\delta f = \{S, f_0\}$. It has been shown that Nemes, Piza and da Providencia (1987); Brink and da Providencia (1989); Nielsen and da Providencia (1989) for small fluctuations, the Vlasov equation may be replaced by the equation for the time evolution of the generator S:

$$\frac{\partial S}{\partial t} + \{S, h_0\} + \delta h = 0 \tag{141}$$

Assuming an interaction of electrostatic origin (Coulomb), the dynamics of positive ions and electrons are described, respectively, by

$$\frac{\partial S_1}{\partial t} + \{S_1, h_0^{(1)}\} + \delta h^{(1)} = 0$$
$$\frac{\partial S_2}{\partial t} + \{S_2, h_0^{(2)}\} + \delta h^{(2)} = 0 \tag{142}$$

We may treat the positive ions nonrelativistically, because they are heavy, and the electrons relativistically, because they are light, so we write, for positive ions, $h_0^{(1)} = p^2/(2M)$, and for electrons $h_0^{(2)} = \sqrt{p^2 + m^2}$. For neutral matter, the density of positive ions must be the same as the density of electrons, so we assume $f_0^{(1)} = f_0^{(2)} = \theta(p^2 - p_F^2)$, where p_F is the common Fermi momentum. Due to translation invariance we assume that

$$S_1 = e^{\mathrm{i}(\omega t - \mathbf{k}\cdot\mathbf{x})}\hat{S}_1(p, \mathbf{k}\cdot\mathbf{p})$$
$$S_2 = e^{\mathrm{i}(\omega t - \mathbf{k}\cdot\mathbf{x})}\hat{S}_2(p, \mathbf{k}\cdot\mathbf{p}) \tag{143}$$

where $p = |\mathbf{p}|$, that is, a plane wave with wave vector $\mathbf{k}$. Then, we may write

$$\delta h^{(1)} = \frac{4\pi e^2}{k^2}(\rho_1 - \rho_2)$$
$$\delta h^{(2)} = \frac{4\pi}{k^2}e^2(\rho_2 - \rho_1) \tag{144}$$

$$\rho_1 = \int d^3p \left\{S_1, f_0^{(1)}\right\}$$
$$\rho_2 = \int d^3p \left\{S_2, f_0^{(2)}\right\} \tag{145}$$

where $k = |\mathbf{k}|$. Notice that

$$\begin{aligned}\int d^3p\{S_j, f_0\} &= -2\pi i \int p^2\, dp\, d\cos\theta\, 2kp \\ &\quad \times \cos\theta\, \delta(p^2 - p_F^2) \\ &\quad \times \hat{S}_j(p, \cos\theta) \\ &= -2\pi i \int d\cos\theta \cos\theta p_F^2 \\ &\quad \times \hat{S}_j(p_F, \cos\theta)\end{aligned} \tag{146}$$

Thus,

$$\left(\omega - \frac{kp\cos\theta}{M}\right)\hat{S}_1 = \frac{8\pi^2 e^2}{k} \times \int d\cos\theta\ \cos\theta(\hat{S}_1 - \hat{S}_2) \tag{147}$$

$$\left(\omega - \frac{kp\cos\theta}{h_{0F}}\right)\hat{S}_2 = \frac{8\pi^2e^2}{k} \times \int d\cos\theta\, \cos\theta(\hat{S}_2 - \hat{S}_1) \qquad (148)$$

Here, θ denotes the angle between the vectors $\mathbf{p}$ and $\mathbf{k}$, and $h_{0F} = h^{(2)}(p_F)$ is the electron Fermi energy. For $\omega > kp_F/h_{0F}$, a collective mode exists such that

$$S_2 = \frac{C_2}{\omega - \frac{kp_F\cos\theta}{h_{0F}}} \qquad S_1 = \frac{C_1}{\omega - \frac{kp_F\cos\theta}{M}} \qquad (149)$$

where C_1, C_2 are constants to be determined. Since, for $|\omega| > a$,

$$a\int_{-1}^{1} d\cos\theta\, \cos\theta\, \frac{1}{\omega - a\cos\theta} = -2 + \frac{\omega}{a}\log\frac{\omega + a}{\omega - a} \qquad (150)$$

the previous ansatz leads to

$$C_1 = \frac{8\pi^2e^2}{k^2p_F}\left(MC_1\left(-2 + \frac{\omega M}{kp_F}\log\frac{1 + \frac{kp_F}{\omega M}}{1 - \frac{kp_F}{\omega M}}\right) - h_{0F}C_2\left(-2 + \frac{\omega h_{0F}}{kp_F}\log\frac{1 + \frac{kp_F}{\omega h_{0F}}}{1 - \frac{kp_F}{\omega h_{0F}}}\right)\right) \qquad (151)$$

$$C_2 = -\frac{8\pi^2e^2}{k^2p_F} \times \left(MC_1\left(-2 + \frac{\omega M}{kp_F}\log\frac{1 + \frac{kp_F}{\omega M}}{1 - \frac{kp_F}{\omega M}}\right) - h_{0F}C_2\left(-2 + \frac{\omega h_{0F}}{kp_F}\log\frac{1 + \frac{kp_F}{\omega h_{0F}}}{1 - \frac{kp_F}{\omega h_{0F}}}\right)\right) \qquad (152)$$

The following dispersion relation is obtained:

$$1 = \frac{8\pi^2e^2}{k^2p_F}\left(M\left(-2 + \frac{\omega M}{kp_F}\log\frac{1 + \frac{kp_F}{\omega M}}{1 - \frac{kp_F}{\omega M}}\right) + h_{0F}\left(-2 + \frac{\omega h_{0F}}{kp_F}\log\frac{1 + \frac{kp_F}{\omega h_{0F}}}{1 - \frac{kp_F}{\omega h_{0F}}}\right)\right) \qquad (153)$$

Approximately,

$$1 \approx \frac{2}{3}\frac{8\pi^2e^2p_F}{\omega^2}\left(\frac{1}{M} + \frac{1}{h_{0F}}\right) \qquad (154)$$

Finally, the plasmon frequency reads

$$\omega_{pl}^2 = \frac{2}{3}8\pi^2e^2p_F\left(\frac{1}{M} + \frac{1}{h_{0F}}\right) \qquad (155)$$

4.5.2
Landau Damping

For $|\omega| < a$,

$$a\mathcal{P}\int_{-1}^{1} d\cos\theta\, \cos\theta\, \frac{1}{\omega - a\cos\theta} = -2 + \frac{\omega}{a}\log\frac{\omega + a}{|\omega - a|} \qquad (156)$$

where $\mathcal{P}$ denotes the principal value.

If $kp_F/M < \omega < kp_F/h_{0F}$, Landau damped modes of the form

$$S_2 = \delta\left(\omega - \frac{kp_F\cos\theta}{h_{0F}}\right) - \frac{C}{\omega - \frac{kp_F\cos\theta}{h_{0F}}} \qquad S_1 = \frac{C}{\omega - \frac{kp_F\cos\theta}{M}} \qquad (157)$$

are also easily obtained. These modes are associated with low-energy excitations.

In figure 4.1 the plasmon frequency is shown as a function of the wave vector. The full line represents the plasmon frequency versus the wave vector, Eq. (153), in arbitrary units. The

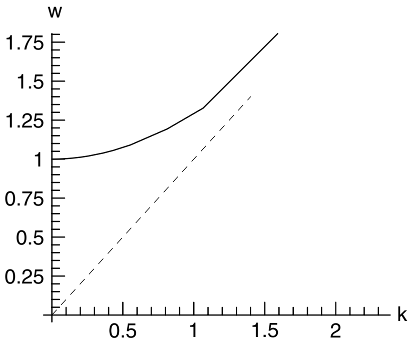

Fig. 4.1 The plasmon frequency, versus the wave vector, in arbitrary units.

dashed line represents the boundary of the region where Landau damping is present, i.e., for a given k, the frequency of the Landau damped mode, Eq. (157), extends continuously from zero to the dashed line.

The formalism described here in this chapter is interesting in the context of evolution equations for electrons and positive ions and as an extension to the single-particle treatment given in the former chapters. The extension has introduced distributions and collective coordinates as in a condensed matter framework. The relevance for such a description is found not only in many-body treatments of plasma systems but also in metallic clusters and could be applied to even metallic molecular clusters or even metalloproteins.

The systems having an amount of positive and negative charges such as positive ions and electrons within a large biomolecule are found in the repair protein, metallothionein, with many metal ions (up to 12 Zn-ions per protein) in a protein pocket containing many negative charges. This protein works as a buffer for Zn-ion signaling inside the cell with a diffusion equation that looks similar to the equations for S_1, S_2. Such a diffusion equation will also make use of distributions and write time derivative of concentrations $[\mathrm{Zn}^+]$ as $d[\mathrm{Zn}^+]/dt = DF([\mathrm{Zn}^+], \nabla[\mathrm{Zn}^+])$.

4.6
Molecular Calculations

In this chapter, we shall show how one can make use of Gaussian wave functions since they are the standard tools in the usual DFT programs that we wish to compare our theory with.

We shall first show some general tools for molecular calculations before going to analyze specific molecules. Basically, we are interested in a proof of the completeness of the current formalism of DFT, or what we call current functional theory (CFT).

When treating molecules, we shall first look at one electron interacting with several nuclei. Later, we shall look at the repulsion between electrons. Since the mass of nucleons is much larger than that of electrons, we shall describe the motion of nuclei classically and also neglect internal excitations corresponding to nuclear dynamics j, h given earlier, so we look at an electronic excitation from the level i with quantum numbers n, m, l and write the wave function

$$\chi_{nlm}(\mathbf{r}+\mathbf{R}) \tag{158}$$

so connected with a nucleus at **R**. It is by the nuclear Coulomb attraction moved to an orbit with quantum number n', m', l' round a nucleus at the origin. So the Coulomb transition matrix element is

$$\int d^3r\chi_{n'm'l'}(\mathbf{r})^* Z/r\chi_{nml}(\mathbf{r}+\mathbf{R}) \tag{159}$$

In the formulation of Shibuya and Wulfman (1965), this amplitude of exciting a state k from a transported χ_i is denoted as

$$\int d^3r\chi_i(\mathbf{r}+\mathbf{R}) = \sum_j \chi_i(\mathbf{r})S(\mathbf{R})^j_i \tag{160}$$

where, in agreement with the earlier,

$$S^j_i = \int d^3r\chi_i(\mathbf{r})^* Z/r\chi_j(\mathbf{r}+\mathbf{R})/k^2 \tag{161}$$

and where the last factor is because of normalization.

The interaction matrix between one electron with transition density $\rho(\mathbf{r})_{\tau'\tau}$ and several nuclei densities, $\rho(\mathbf{X}_a)_{T'T}$, is

$$S_{\tau'\tau} = \sum_a \int \rho_{\tau'\tau} d^3r 1/|r-X| \int \rho_{T'T} \tag{162}$$

Here, we follow (Avery and Shim, 2001) and let τ denote the center of the position of the electron density (of course $= X_a$) as well as its spherical quantum numbers. From the Schrödinger equation of the electron, as well as its consequence, the continuity of transition time-dependent transition densities as in Bang and Hansteen (2002) we arrive at the expression for $S_{\tau'\tau}$

$$S_{\tau'\tau} = \int_j L_{\tau'} J_{T'T}\hbar^2 4\pi d^3r/(E_{\tau'\tau}E_{T'T}) \tag{163}$$

where L stands for the longitudinal component of the transition probability. Since the nuclei are so much heavier than the electrons, we may approximate $J_{T'T}$ with a classical density of point charges, whereas $j^L_{\tau'\tau}$ is still the quantum density of longitudinal currents. Now, the $S_{\tau'\tau}$ obviously forms a representation of the group of translations based on Sturmian bound state densities, for example, as used by Avery and Shim (2001). The character of this group is just identical to the densities of currents as defined by Gross *et al.* (1996) . Thus, the completeness of the currents and densities is readily seen.

4.6.1
Gaussian Integration

Next we return to the Gaussian integration tools.

With a Gaussian expansion for the wave functions, it is natural to start from expression (136)

$$j(r)^L_{ki} = \text{grad}_r \int dr'^3 \rho(r')_{ki} \mathrm{i} E_{ki}/((r_-)4\pi\hbar) \tag{164}$$

$$Y_{J,J-1,M} \quad \text{for} \quad A = J+1 \tag{165}$$

$$Y_{J,J+1,M} \quad \text{for} \quad A = -J \tag{166}$$

each Gaussian term now get a radial form

$$w(r) = r^{-A}\int_0^r dr' r'^A \rho(r')C \tag{167}$$

where $A = J+1$ when the vector spherical harmonics is $Y_{J,J-1,M}$, but $A = -J$ for $Y_{J,J+1,M}$. The argument from (Bang and Hansteen, 2002), that Eq. (167) will lead to finite integrals, independently of the sign of A, is still valid. Let us look at one term in a Gaussian expansion of an ordinary electron density

$$j(r)^L_{kk}/E_{kk} = \int dr'^3 \mathrm{grad}_{r'} \times \rho(r')_{kk} \mathrm{i}/(4\pi\hbar|r_-|) \quad (168)$$

Considering one term in a Gaussian expansion of an electron density (an ordinary, nontransition density) $\rho(\mathbf{r})_{kk}$, we can use the above formula to get

$$\begin{aligned} \mathrm{grad}_r[\rho(r)] &= \mathrm{grad}_r(F(r)Y_{JM}) \\ &= -\sqrt{(J+1)/(2J+1)} \\ &\quad \times (d/dr - J/r)F(r)Y_{J,J+1,M} \\ &\quad + \sqrt{J/(2J+1)} \\ &\quad \times (d/dr + (J+1)/r)F(r)Y_{J,J-1,M} \end{aligned} \quad (169)$$

The two terms correspond to $A = -J$, respectively, $A = J + 1$.

$$F(r) = e^{-\beta r^2} \quad (170)$$

each radial differential equation has the solution

$$r^A \int dr'(r')^{-A}F(r') \quad (171)$$

When the F's are error functions, the integrals are given by

$$\int_{-\infty}^{0} (r')^A e^{-\beta(r')^2} = 1/2(-1)^A(\beta)^{(-1-A)/2}\Gamma[(1+A)/2] \quad (172)$$

$$\int_0^r (r')^A e^{-\beta(r')^2} = 1/2r^{1+A}(r^2\beta)^{1/2(-1-A)} \times \left(\Gamma[(1+A)/2] - \Gamma[(1+A)/2, r^2\beta]\right) \quad (173)$$

The Gaussian densities, with their short ranges are of course not very fit for calculation of the effects of the long-range Coulomb interactions, but since they are easy to calculate, they are widely used.

The vector spherical harmonics are orthogonal in the way that their scalar products, integrated over all the relevant space, are only different from zero if all three of their quantum numbers [J,l,M] are identical. So we get, for the energy term corresponding to the interaction between two electrons, where one goes between the states k and i, the other between the states j and h, the transitions called, respectively, α and β

$$I^L_{J,\alpha,\beta} = \int_0^\infty drr^2((F^L_{\alpha,J+}F^L_{\beta,J+}) + (F^L_{\alpha,J-}F^L_{\beta,J-}) \quad (174)$$

where

$$F^L_{\alpha,J+}(r) = -\sqrt{(J+0)/(2J+1)} \times (d/dr - (J+0)/r)F(r) \quad (175)$$

$$F^L_{\alpha,J-}(r) = +\sqrt{(J+1)/(2J+1)} \times (d/dr + (J+1)/r)F(r) \quad (176)$$

and so on.

4.6.2
The Case of the ZnO Molecule

As an example of the use of the suggested method, we shall look at the molecule of ZnO. Although this is not organic, it plays an important role in many organic compounds. We shall here, as suggested in Bang and Hansteen (2002), use elliptic coordinates, which separate the kinetic energy operator, and also the potential energy of one electron in the Coulomb potential from nuclei at rest, when it can be written in the form

$$V = (V_I(r_1 + r_2) + V_{II}(r_1 - r_2))/r_1 r_2(+V(\phi \cdots)) \tag{177}$$

Here, r_1 and r_2 are the distances of the electron to nuclei 1 and 2, respectively, and ϕ the angle of the position of the electron around an axis through both nuclei. The standard elliptical coordinates are now ϕ and

$$\xi = (r_1 + r_2)/R \tag{178}$$

$$\eta = (r_1 - r_2)/R \tag{179}$$

Here, R is the distance between the two nuclei. To get simple formulas, we chose units so that this distance is 2. The components of the gradient of the electron transition density are now

$$\left[\mathrm{grad}_\phi,\ \mathrm{grad}_\xi,\ \mathrm{grad}_\eta\right]\rho \tag{180}$$

which we shall list below in the same order:

$$\sqrt{(1 - cos^2\phi)/((\xi^2 - 1)(1 - \eta^2))}\,\partial\rho_{ki}/\partial\phi \tag{181}$$

$$\sqrt{(\xi^2 - 1)/(\xi^2 - \eta^2)}\,\partial(\rho_{ki})/\partial\xi \tag{182}$$

$$\sqrt{(1 - \eta^2)/(\xi^2 - \eta^2)}\,\partial(\rho_{ki})/\partial\eta \tag{183}$$

Omitting the spin again, the solution of the one-electron Schrödinger equation in elliptical coordinates has the form

$$\psi_{k,|m|}(\xi, \eta)e^{im\phi} = \sum_{n=0,l=|m|} c^k_{n,l,|m|} e^{im\phi} P_l^{|m|}(\eta) F_{k,n,|m|}(\xi) \tag{184}$$

Here, the solutions in terms of the η, ϕ coordinates are well known and simple, whereas the F functions in terms of ξ are only known in special cases. They are, nevertheless, easy to find from the separated Schrödinger equation in elliptical coordinates. As a rough approximation, we may take the number of relevant states as being the same as the number of Gaussian states in the single particle atomic orbital approximation, that is, with spin 54 basis functions. In the atomic orbital approximation, 22 of these are concentrated around O, the other 32 are concentrated around Zn. Overall, we see that it is possible to get an understanding of the occupation probability by taking the square of the equation given earlier, which mainly mounts to taking the square of $F_{k,n,|m|}$.

4.6.3
The Case of a Water Molecule

Although H_2O is again an inorganic molecule, it also plays a large role in many organic compounds and reactions. It is interesting as an example of a more complicated use of the suggested method

$$\chi(H_2O) = A\chi_1(H)\chi_2(H)\chi(O) \tag{185}$$

Here, A is an antisymmetrizing operator on the electron wave functions. It is not so important, because the electron wave functions for different atoms in a molecule have rather small overlaps. We treat the nuclei in a classical approximation. Now, the hydrogen electron wave functions are Shibuya–Wulfman integral factors (Shibuya and Wulfman, 1965; Avery and Shim, 2001), translated to the center of the oxygen atom

$$\chi_{i,\nu}(\mathbf{x} + \mathbf{R_i}) = \sum_{\nu'} \chi_{\nu'}(\mathbf{x}) S^{\nu}_{\nu'}(\mathbf{R_i}) \tag{186}$$

Hence the product of the two hydrogen functions in Eq. (185) becomes

$$A\chi_{1,\nu}(\mathbf{x})\chi_{2,\nu'}(\mathbf{x})\sum_{\nu''} S_{\nu'}^{\nu''}(\mathbf{R}_1)S_{\nu''}^{\nu}(\mathbf{R}_2) \tag{187}$$

Owing to the group properties of the Shibuya–Wulfman factors, the last sum of products of these can be written as

$$\sum_{\nu''} S_{\nu'}^{\nu''}(\mathbf{R}_1)S_{\nu''}^{\nu}(\mathbf{R}_2) = S_{\nu'}^{\nu}(\mathbf{R}_1+\mathbf{R}_2) \tag{188}$$

Although this expression looks a little complicated, it must be remembered that the Shibuya–Wulfman integral factors are an extremely useful tool in any molecular calculation. The square of the factor $S_{\nu'}^{\nu''}(\mathbf{R}_1)$ is a transition probability between ν and ν' states. These factors will hopefully be part of numerical projects such that programs for their calculation at different values of $\mathbf{R}_{\rm ij}$ should be available in the near future at centers of such calculations, thereby solving one main problem of these calculations: the interaction between electrons and nuclei for different configurations. The other main problem, the interaction between electrons, may then be solved by the methods suggested here or by some modifications of those.

In Bang and Hansteen (2002) one method of describing the Coulomb interaction between electrons in atoms and molecules was given. Here, we shall suggest a similar method for the interactions between electrons and nuclei. We start from Eq. (4) of Bang and Hansteen (2002). Let the quantum numbers of an electron orbital around a nucleus (charge Z) at $\mathbf{R}$ be nlm. In the following, we suppress lm and denote the orbital $\chi_n(\mathbf{r}+\mathbf{R})$ and an (excited) orbit $\chi_{n''}$. Similarly, we denote the states of the nucleus $\chi_{N'}$, $\chi_{N''}$. As in Bang and Hansteen (2002) the general Coulomb matrix element is

$$C\int dr^3 \int dr'^3 div j_{n''n} div j_{N''N'}/|r-r'| \tag{189}$$

but since r' is now the coordinate of a nucleus, we may assume, that its deviation from 0 is negligible, and just write a classical approximation (also neglecting its internal excitations)

$$j_{N''N''} = C_N\delta(r') \tag{190}$$

We then get the amplitude for exciting the electron from an orbital χ_n around $\mathbf{R}$ to another orbital $\chi_{n''}$ around 0 by means of the Coulomb field from a nucleus at 0:

$$C\int dr^3\chi_{n''}^*(\mathbf{r})Z/r\chi_n(\mathbf{r}+\mathbf{R}) \tag{191}$$

Note that the relations between transition charge densities and transition current densities are general and do not depend on whether the normalization is Schrödinger or Sturmian, or on the orthogonality of χ_n, $\chi_{n''}$; not even on whether the argument of the χ is $\mathbf{r}$ or $\mathbf{r}+\mathbf{R}$. Introducing C above as the reciprocal of the double kinetic energy of electrons (common to all Sturmian states) we get our amplitude equal to the $S_{n''}^{n}(\mathbf{R})$ introduced by Shibuya and Wulfman in their important work on molecular electronic wave functions. Using Sturmian states also for the complete molecular wave function, we come to the same secular equation as these authors:

$$\sum_{\tau}[\nu_{\tau'\tau} - k_\mu S_{\tau'\tau}]C_{\tau\mu} = 0 \tag{192}$$

Here, the index τ includes both the quantum numbers nlm and an index describing the position of the various nuclei of the molecule; the ν matrix represents the interaction between one electron and the totality of nuclei of the molecule. The solution of this secular equation thus gives the motion of one electron. To solve the total molecular problem, one should then include the effect of electron–electron interaction, which is the main theme of this paper, and add the classical description of the motion of nuclei, including their repulsion from each other, all three steps might be repeated to convergence.

In the Shibuya and Wulfman (1965) paper, much work is connected to the introduction of a momentum space representation of electron wave functions. Nevertheless, the final expression for their S is written in position space, like here.

4.7
Numerical Treatments

We shall finish the review with a proposal of how one could treat the electronic time development equations derived earlier, for larger molecular systems. This will make use of some of the modern computer software for deriving physical properties of molecules on the basis of their crystallographic databases. Many of the algorithms for these tasks are embedded in the molecular dynamics program packages.

Let us briefly describe here one of such procedures we have in mind, by giving the following example of a large molecular system. An example that illustrates the importance and usefulness of solving our equations of the time development of the electronic systems is zinc molecules or molecules where zinc atoms are incorporated. We have especially the proteins that contain copper ligands of which one medium-sized protein is alcohol dehydrogenase.

The first step is, as for any molecular dynamics simulations that do not start from *ab initio* configurations, to obtain the full set of atomic cartesian coordinates representing the initial configuration. This set of coordinates is obtained from the X-ray crystallographic databank. One might ask if that is necessary for a quantum mechanical calculation, but an initial molecular dynamics energy minimization is always required for positioning the surrounding solvent molecules such as water and other ligands and this classical molecular dynamics is also in our case necessary before solving for quantum time trajectories.

Once this initial molecular dynamics equilibration is performed, we can ask for electrostatic configuration, which is the next input to our electronic time-dependent equations. We wish to have the field strength tensor constructed and that is done either from a multipole expansion or directly from the force field where fields are obtained from the nablaient of the energy potentials built up from the atomic coordinates, the bond lengths and the bond angles. One of the basic effects of the charges in the molecule is to induce dipoles in the surroundings, given basically by the potential from the work the charges are performing: $V_o = 1/2\alpha E^2$.

4.7.1
Comparison of the Standard DFT's and Our Method's Numerics

In the following section, we shall describe how one can assess the various numerical treatments of the molecules

Tab. 4.1 A comparison of the different calculations of occupation probabilities (Mulliken) in atomic orbitals (AOs) of oxygen in various simple molecules. The two methods that are compared are the standard Density Functional Theory (DFT) calculation with Gaussian error functions and our method BB (Bang-Bohr) presented by spherical harmonics. The population is according to the Mulliken-prescription, that is, core contribution minus valence. The py and pz occupations are the same. Both spin states are listed as s_1/s_2. Therefore only px and py are significant.

Calculated occupation numbers						
Molecule type (MD)	**AO 2s (DFT)**	**AO px (DFT)**	**AO py (DFT)**	**AO 2s (BB)**	**AO px (BB)**	**AO py (BB)**
ZnO_2	1.02/0.95	0.65/0.43	1.03/0.74	1.05/0.98	0.62/0.41	1.01/0.72
$4H_2O$	0.90/0.91	1.00/0.71	0.97/0.69	0.94/0.95	0.97/0.69	0.94/0.67

mentioned earlier. We shall, within these examples, compare the numbers about electronic orbitals calculated with the help of usual theoretical DFT techniques and techniques based on our electronic wave equations.

We give the results from a DFT calculation of the small molecules using the Gaussian program from where we have listed all the occupation probabilities of the available quantum states. Thus, we can employ the formulas derived earlier to derive the occupation numbers from our method.

The first case we have studied numerically is the zinc-oxide molecule. In Table 4.1 we have listed the occupation probabilities of the electrons in the various ground states.

As is seen from the table there is reasonable agreement of the stationary population statistics in the lower atomic orbitals of the two methods. Our method is supposed to be superior with respect to excited state dynamics, the transition amplitudes, and other time-dependent quantities. However, it is hard to find other numbers to compare with than the stationary population dynamics.

Appendix A: Gaussian Expansions and Numerical Calculations

In the following, we want to compare results with standard DFT calculations using Gaussian functions. Hence, we shall, for the purpose of comparisons, introduce Gaussian expansions of the wave functions and similarly of the density ρ and its derivatives that are also taken as Gaussian like. It is thus natural to start from the current expression:

$$j^L_{ki} = \nabla_r \int dr'^3 \rho(r')^A_{ki} \mathrm{i} E_{ki}/((r-)4\pi\hbar) \times Y_{J,J-1,M} \tag{A1}$$

and each Gaussian term now gets a radial form:

$$w(r) = r^{-A} \int_0^r dr' r'^A \rho(r') C' \tag{A2}$$

The argument from Bang and Hansteen (2002) that concerns the finiteness of the integrals given earlier, independent of the sign of A, is still valid. Actually, extending the upper integration limit to infinity renders these Gaussian integrals manageable, such that

$$\int_0^\infty e^{-\lambda x^2} x^k = 1/2\lambda^{-(k+1)/m}/\,\Gamma(k+1/m) \tag{A3}$$

showing that no singularities are occurring in this formalism. The integrals, which we shall use, are of the form

$$Q(r) = -\sum_i \int dr' \int dr'' \psi_i(r)^* \times G_i(r, r') V_e(r', r'') \psi_i(r'') \tag{A4}$$

which can be simplified, using the procedures of Eqs (A2) and (A3), to

$$r^{-A} \int_0^r dr' (r')^A C \int_0^{r'} dr'' e^{[-r''^2]} \tag{A5}$$

where $A = J + 1$ corresponds to the vector spherical harmonics to be $Y_{J,J-1,M}$ but, in the case of $A = -J$, becomes $Y_{J,J+1,M}$. Considering just one term (diagonal) in a Gaussian expansion of an electron density (an ordinary, nontransition density) $\rho(r)_{kk}$, we can use the formula given earlier to get

$$\frac{j(r)^L_{kk}}{E_{kk}} = \int dr'^3 \nabla'_r \rho(r')_{kk} \mathrm{i}/84\pi\hbar \tag{A6}$$

where

$$\begin{aligned}\nabla_r[\rho(r)] &= \nabla_r(F(r)Y_{JM}) \\ &= -\sqrt{(J+1)/(2J+1)} \\ &\quad \times (d/dr - J/r)F(r)Y_{J,J+1,M} \\ &\quad + \sqrt{J/(2J+1)} \\ &\quad \times (d/dr - J/r)F(r)Y_{J,J-1,M}\end{aligned} \tag{A7}$$

The two terms correspond to $A = -J$ and $A = J + 1$, respectively. Terms with negative A can be eliminated in the radial integral, where the F functions now are of the Gaussian type. This can be seen by using a recursive procedure, repeated some times

$$\mathrm{i}^n \operatorname{erfc}(z) = -z/n\mathrm{i}^{n-1} \operatorname{erfc}(z) + 1/(2n)i^{n-2} \operatorname{erfc}(z) \tag{A8}$$

or

$$\begin{aligned}2(n+1)(n+2)\mathrm{i}^{n+2} \operatorname{erfc}(z) &= (2n+1+2z^2) \operatorname{erfc}(z) \\ &\quad - 1/2\mathrm{i}^{n-3} \operatorname{erfc}(z)\end{aligned} \tag{A9}$$

where erfc is the error function.

Appendix B: Transition Charge Density

For the sake of consistency of the chapter, this appendix brings a derivation of the expression, following the prescription of the Bang and Hansteen (2002) for the transition current densities that are used in Sections 4.2.1 and 42.2 of the present chapter. We start, as in Bang and Hansteen (2002), from an expression for the one-particle transition charge density:

$$\rho(r)_{ki} = e\psi(r)^*_k \psi(r)_i \tag{B1}$$

where $\psi(r)_k$, $\psi(r)_i$ are the one-particle energy eigen states and where the numbers i, k stand for the radial, angular momentum, and so on. The perturbative matrix element for the residual Coulomb interaction between two electrons situated at r and r' is then expressed by the integral

$$I_C = \int dr^3 \int dr'^3 \frac{\rho(r)_{ki}\rho(r')_{jl}}{|\,r - r'\,|} \tag{B2}$$

and applying the time-dependent Schrödinger equation for ψ the integral can be written as

$$I_C = -\int dr^3 \int dr'^3 \frac{1}{| r - r' |} \frac{\partial \rho(r)_{ki}}{\partial t} \times \frac{\partial \rho(r')_{jl}}{\partial t} (E_{ki} E_{jl})^{-1} (\hbar)^2 \qquad \text{(B3)}$$

where $E_{ij} = E_i - E_j$. If again the continuity equation of transition charge densities is applied, one can write the integral I_C as follows:

$$I_C = -\int dr^3 \int dr'^3 \frac{1}{| r - r' |} \times div_r \mathbf{j}(\mathbf{r})_{ki} div_{r'} \mathbf{j}(\mathbf{r}')_{jl} (E_{ki} E_{jl})^{-1} (\hbar)^2 \qquad \text{(B4)}$$

with j_{ij} being the transition current:

$$\mathbf{j}_{ij} = a(\psi_i^* \nabla \psi_j - \psi_j \nabla \psi_i^*) \equiv \mathbf{j}^\alpha \mathbf{j}^\beta \qquad \text{(B5)}$$

where $a = \frac{e\hbar}{2mi}$ and where α, β correspond to the quantum numbers of the interchange of the states i, j. One should remark that, fortunately, if the denominator E_{ij} is zero, then the numerator is also zero.

We are now in a position to derive the very important expressions for the current, which are used in Chapter 3. These expressions have been derived with the powerful tool of vector algebra where the vectors, in this case the transition current densities, are split into longitudinal parts, j^L, and transverse parts, j^T, as seen later:

$$\mathbf{j}(\mathbf{r})^L = -\mathrm{grad}_r \int d\mathbf{r}'^3 div_{r'} \times \mathbf{j}(\mathbf{r}') \frac{1}{(4\pi \mid \mathbf{r} - \mathbf{r}' \mid)} \qquad \text{(B6)}$$

which in terms of densities is:

$$\mathbf{j}(\mathbf{r})_{ij}^L = \int dr'^3 \mathrm{grad}_{r'} \boldsymbol{\rho}(\mathbf{r}')_{ij} \frac{iE_{ij}}{(4\pi \mid \mathbf{r} - \mathbf{r}' \mid \hbar)} \qquad \text{(B7)}$$

and

$$\mathbf{j}(\mathbf{r})^T = \mathrm{rot}_{r'} \int d\mathbf{r}'^3 rot_{r'} \mathbf{j}(\mathbf{r}') \frac{1}{(4\pi \mid \mathbf{r} - \mathbf{r}' \mid)} \qquad \text{(B8)}$$

which altogether can be written as $\mathbf{j} = \mathbf{j}^L + \mathbf{j}^T$.

With these expressions inserted in Eq. (A2) and subsequently performing a partial integrations, one finally obtains

$$I_C = \frac{\hbar^2 4\pi}{E_{ij} E_{kl}} \int d\mathbf{r}^3 \, \mathbf{j}(\mathbf{r})_{ki}^L \, \mathbf{j}(\mathbf{r})_{jl}^L \equiv \frac{\hbar^2 4\pi I^L}{E_{ij} E_{kl}} \qquad \text{(B9)}$$

which therefore transform the sixth dimensional integral at the start of the appendix to a much simpler three-dimensional integral of the scalar product of the two transition current densities. There are similar expressions valid for the transverse component. However, only the longitudinal ones are used for the calculation of the Coulomb matrix elements.

5.1
Construction of Light Harvesting and Energy Converting Pigment Systems of Photosynthesis

There is a large variety of photosynthetic organisms ranging from very old photosynthetic bacteria containing only one photosystem to more recently evolved cyanobacteria, algae, and green plants having two photosystems operating in series and capable of water oxidation and oxygen production. Despite large differences in composition and architecture of the pigment–protein systems of various organisms, the overall function of most photosynthetic light energy converting systems is surprisingly similar. Thus, it is generally seen that light is very efficiently collected by a light-harvesting antenna and within ~100 ps it is transferred to the photochemical reaction center (RC) where the light energy is converted to a stable charge-separated state with almost 100% quantum efficiency creating a transmembrane potential, which is the source of energy for all subsequent processes in the organisms (vanGrondelle, 1985; vanGrondelle *et al.*, 1994; Pullerits and Sundstrom, 1996; Sundstrom, Pullerits and vanGrondelle, 1999). This general pattern of overall time scale of the primary photosynthetic processes can easily be understood as a combined result of the high (~95%) overall quantum efficiency of light-to-charge conversion and the known nanosecond fluorescence lifetimes of many photosynthetic pigments (chlorophyll, bacteriochlorophyll, phycocyanin, etc.). To efficiently compete with fluorescence deactivation of the excited states, the functional energy and charge transfer processes have to be at least 10–100 times faster. These requirements for efficient conversion of light energy into chemical energy in pigment systems, which are robust against changes in environmental factors, variation in light intensity, presence of reactive species, and variation in pigmentation and structure, have through the eons of evolution led to a number of "design principles" that can be recognized in most photosynthetic systems. In what follows, we will identify the most important concepts and discuss how they contribute to achieve an efficient light harvesting and converting process. In the search for efficient man-made devices for solar energy conversion, the principles of nature are very interesting to pursue.

5.2
Need for a Light-Harvesting Antenna

Natural photosynthesis utilizes two coupled pigment systems, a light-harvesting antenna and a photochemical RC, for efficient conversion of light energy into stabilized charges, eventually used to synthesize chemically stable high-energy products. This is well illustrated by the photosynthetic unit (PSU) of purple bacteria (Figure 5.1a), where two different antenna systems, the LH2 peripheral antenna (smaller circles) and the core LH1 antenna (bigger circle), are surrounding the photosynthetic RC inside of LH1. Both pigment systems are absolutely essential for the operation of photosynthesis. The light-harvesting antenna is composed of a large number (~100) of pigment molecules, whose task is to collect sunlight over a broad spectral range and efficiently deliver it to the RC. The RC consists of a few highly specialized pigment molecules, whose organization and interactions are fine tuned to optimize unidirectional electron transfer across the photosynthetic membrane, achieving a long lived charge-separated state with high efficiency. In oxygenic photosynthesis, the oxidizing power of this charge-separated state is used to extract electrons from water, with the help of a catalytic manganese cluster.

The need for a coupled antenna–RC system is easily realized by considering the fact that the photochemical reaction in photosynthesis, splitting of water and formation of molecular oxygen, requires four photochemical cycles of the RC to occur in quite short time (typically milliseconds). On longer time scales, all charge-separated states undergo recombination reactions to the ground state, causing loss of the acquired photon energy. Owing to this constraint, without an antenna system coupled to the RC the conversion efficiency of a photosynthetic system would be very low at the ambient light fluxes delivered by the sun. Thus, an antenna coupled to a photochemical RC unit is a necessary feature for efficient photocatalytic operation at ambient solar light intensities. This is also an important lesson to learn from nature for constructing of an artificial solar energy conversion system. Figure 5.1a–d shows a few examples of photosynthetic antenna–RC pigment systems from different types of organisms. Their function is discussed below.

5.3
Spectral Coverage

Photosynthetic organisms live in habitats with greatly varying conditions of light intensity and spectral distribution. Land-based plants are exposed to the full solar spectrum, whereas organisms living in water or in the soil all are exposed to a more or less heavily filtered solar spectrum. This implies that species have developed their pigment composition to optimize light collection in each specific location. This fact is illustrated in Figure 5.2, where the solar spectrum is reproduced along with characteristic regions of light absorption of different organisms and pigments. Thus, we can see that the useful parts of the solar spectrum from the blue (~400 nm) to the near-infrared (~1100 nm) is completely covered by various pigments without any gaps; nature has devised pigment systems and organisms have evolved to efficiently harvest all colors of the sunlight impinging on the Earth. variety of pigmentation is integrated into a range of functional pigment–protein structures. In Figure 5.1 we show just a few examples to illustrate the great structural diversity of the photosynthetic pigment apparatus construction. In photosynthetic purple bacteria, both antenna and RCs are transmembrane proteins fully integrated into the photosynthetic membrane (Figure 5.1a). The antenna consists of a circular core antenna LH1 surrounding the RC and a peripheral LH2 complex also of circular shape. High-resolution crystal structures have been obtained for both LH1 (Roszak *et al.*, 2003) and LH2 (Mcdermott *et al.*, 1995). The pigments of these antennas have well-separated absorption and fluorescence spectra and the high symmetry of the complexes makes them amenable for quantum chemistry calculations and computer simulations of energy and electron transfer processes. It also turns out that the antennas of purple bacteria constitute a representation of various energy transfer mechanisms. Antennas and RCs of purple bacteria have therefore served as test grounds for studies of energy and electron transfer in photosynthesis; much of our knowledge today about these processes stems from studies of purple bacterial pigment–protein complexes. In cyanobacteria (Figure 5.1b) there is an extramembrane antenna, the phycobilisome (Gantt, 1981), attached to the thylakoid membrane holding the core antenna and the photochemical RC. The chromophores of phycobilisomes are open-chain tetrapyrolles (phycoerythrin, phycocyanin, and allophycocyanin) arranged in such a way that downhill energy transfer (from high- to low-energy pigments) occurs toward the membrane and chlorophyll containing core antenna and RC (vanGrondelle *et al.*, 1994). The overall construction of the photosynthetic pigment apparatus of green sulfur bacteria (Figure 5.1c) is reminiscent of that of cyanobacteria. Here, a large antenna containing thousands of bacteriochlorophyll molecules arranged in rod-like structures and encapsulated in cigar-shaped structures (chlorosomes) (Olson, 1980) are attached via a baseplate and a linking pigment–protein complex (the so-called Fenna-Mathews-Olsen (FMO) Fenna and Matthews, 1975, complex) to the membrane. One chlorosome can funnel energy to 10–15 RCs. To conclude this survey of different PSUs, we consider that of green plants consisting of the two photosystems PS1 (Jordan *et al.*, 2001) and PS2 (Zouni *et al.*, 2001; Ferreira *et al.*, 2004) (Figure 5.1d), operating in series. Here, chlorophyll *a* and chlorophyll *b* are the main chromophores of both antenna and RCs, and despite the presence of many different pigment–protein complexes, the spectral properties are quite similar. This difficulty to spectroscopically distinguish different parts of the photosynthetic apparatus has delayed a detailed understanding of energy and electron transfer pathways and mechanisms. However, using the most powerful spectroscopic methods combined with theoretical modeling, important progress has been made.

5.4
Efficient Energy Flow Through the Light-Harvesting Antenna Systems

Examination of different photosynthetic antennas reveals one of nature's remarkable achievements – despite often very large antennas of hundreds or sometimes even thousands of pigment molecules, all of them are coupled to each other such that energy flows through the system and is channeled into the RC with a total quantum conversion efficiency approaching unity. How remarkable this design is, may be best appreciated when one tries to build an artificial pigment system for light harvesting – it is very difficult to make a large system containing many pigment molecules that are all well-coupled and at the same time avoid excited state quenching. The distance dependence to the sixth power of Förster energy transfer (Forster, 1946), generally active in photosynthetic systems, implies that molecules have to be within ~1 to 3 nm for efficient energy transfer. If the distance is shorter, excited state quenching often occurs and efficiency decreases. Nature has solved this problem by using proteins that hold the pigment molecules in well-defined and fixed positions, which optimize energy transport and minimize quenching processes. In the PS1 and PS2 antennas (Figure 5.1d) more than half the mass is pigment and (Figure 5.1c) there is no protein in the interior of the chlorosome; the bacteriochlorophyll-*c* molecules are self-assembled into a very ordered aggregate. Nevertheless, the excited state lifetimes of the pigments in antennas are generally ~1 ns and there is plenty of time for energy transfer over quite long distances. As we will see below, typical energy transfer times between two pigment molecules are subpicosecond to few picoseconds (vanGrondelle *et al.*, 1994; Pullerits and Sundstrom, 1996; Sundstrom, Pullerits and vanGrondelle, 1999; Sundstrom *et al.*, 1986).

We will use the photosynthetic apparatus of purple bacteria (Figure 5.1a) to illustrate the concepts just discussed, since it contains spectrally and structurally distinct pigment systems, implying that using the tools of time-resolved spectroscopy we can, in detail, monitor the flow of energy through the antenna and relate observed dynamics to structural features.

Figure 5.3a illustrates the absorption spectrum of the purple bacterial PSU (Figure 5.1a), demonstrating the two infrared absorption bands of LH2 characteristic of the B800 and B850 pigments, as well as a red wing due to the LH1 core antenna. The RC absorption is overwhelmed by the absorption of many more LH1 antenna molecules. Energy flow through the pigment system can be monitored with time-resolved fluorescence or transient absorption spectroscopy. The well-separated spectral bands of the different pigments facilitate the resolution of the various transfer steps. This is illustrated by the time-resolved transient absorption spectrum of a purple bacterial PSU in Figure 5.3b. The peripheral LH2 antenna

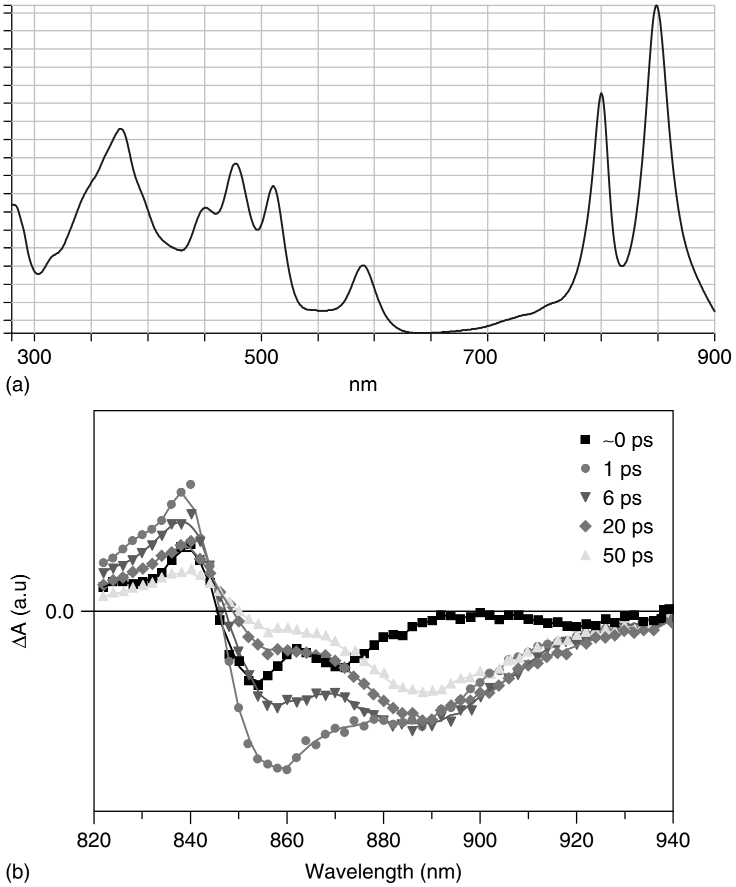

Fig. 5.3 (a) Absorption spectrum of the purple bacterial PSU. (b) Time evolution of the transient absorption spectrum of the purple bacterial photosynthetic unit, following excitation of the LH2 antenna with an ultrashort optical pulse.

was excited with an ultrashort femtosecond laser pulse. At the earliest times, after photoexcitation the B800 and B850 bands are bleached due to the direct optical excitation. On the tens of picosecond time scale the low-energy bands of LH1 and the RC grow in intensity at the expense of the higher energy LH2 bands, showing that the energy has reached the RC within this time (vanGrondelle *et al.*, 1994; Sundstrom, Pullerits and vanGrondelle, 1999; Sundstrom *et al.*, 1986).

Energy transfer from an LH2 to an LH1 ring was studied in a membrane preparation of *Rhodobacter sphaeroides* and concluded to be characterized by a ∼5 ps transfer time, consistent with the estimated inter-ring distance. Transfer between aggregated B850 rings was studied using time-resolved excitation annihilation combined with a Monte Carlo simulation, together with transmission electron microscopy (TEM) (Schubert *et al.*, 2004). The random-walk Monte Carlo calculation showed that the ring-to-ring hopping time is ∼30 ps and the number of B850 rings in an aggregate is ∼15, in good agreement with the spot size observed in the TEM images (Schubert *et al.*, 2004). The ring-to-ring hopping time of ∼30 ps implies that for a B850 ring surrounded by six neighboring rings the excitation residence time is ∼5 ps. This time is in good agreement with the 3–8 ps LH2–LH1 transfer time obtained for native membranes (Hess *et al.*, 1995; Nagarajan and Parson, 1997; Freiberg *et al.*, 1989).

Upon inspecting the structures of, for instance, the purple bacterial (Figure 5.1a) and PS1 (Figure 5.1d) PSUs the concept of multiple energy transfer pathways becomes obvious, that is from a given point in the antenna system there are many possible paths to reach the RC. This is a design principle that renders high efficiency and robustness to the antenna system. In the purple bacterial PSU, LH2 rings are connected to other LH2s as well as to LH1, implying that if an excitation in an LH2 ring for some reason is disconnected from the LH1 core antenna, it can always find an alternative path through other LH2s. Once in LH1, the excitation can enter the RC from any point on the LH1 circle. The multiple pathways of energy transfer in combination with the very fast (hundreds of femtosecond time scale) energy transfer within B850 of LH2 and LH1 result in a very fast and efficient percolation of excitation energy over the photosynthetic pigment system. The energy gradient of the light-harvesting pigments toward the core antenna and RC results in the observed very fast and efficient (∼50 ps and close to 100% quantum efficiency) overall transfer of excitations from antenna to RC.

5.5
Intracomplex Energy Transfer

Using biochemical methods, individual pigment–protein complexes can be isolated from the photosynthetic membrane. Spectroscopic studies of such preparations offer additional detail about the photosynthetic processes. We give one example, B800 to B850 energy transfer in the LH2 complex (Figure 5.1a). The BChls of B800 are well separated from each other and from the B850s and thereby have mainly monomeric spectroscopic properties. Excitation absorbed in the B800 ring is first transferred among B800 BChls (Sundstrom, Pullerits and vanGrondelle, 1999). Calculations based on the Förster theory (Forster, 1946) agree remarkably well with the measured

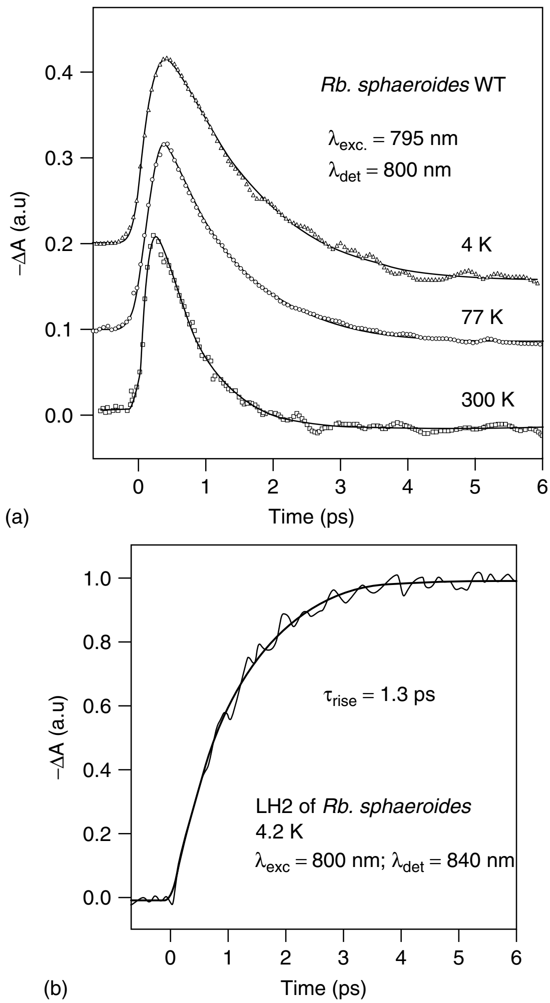

Fig. 5.4 Transient absorption kinetics illustrating energy transfer from B800 to B850 in LH2. B800 is excited by a femtosecond pulse at 800 nm and the energy transfer is monitored in (a) as the decay of B800 excited state population, and in (b) as the corresponding rise of B850 population. The transfer becomes somewhat slower at low temperature.

pairwise transfer time of 300 fs, suggesting that for the B800 ring the point-dipole approximation is applicable. Also low temperature transient absorption anisotropy kinetics measured at different wavelengths inside the B800 band were successfully simulated by a model of Förster hopping in a spectrally inhomogeneous ring of BChl molecules. B800 to B850 transfer occurs with a time-constant of 0.7 ps at room temperature (Sundstrom, Pullerits and vanGrondelle, 1999) and it slows down upon lowering the temperature to 1.2 ps at 77 K and to 1.5 ps at 4 K (Figure 5.4). Both B800 and B850 can be spectrally tuned by selective mutations of key amino acids and the B800 BChls can be exchanged to other similar BChl and Chl pigments (Sundstrom, Pullerits and van-Grondelle, 1999; Fraser *et al.*, 1999). A series of pigment–protein complexes, where either the B800 or B850 band was spectrally shifted, were studied and significant changes of the transfer time were observed (Sundstrom, Pullerits and vanGrondelle, 1999; Herek *et al.*, 2000). The complex with the most blue-shifted B800 pigment, at 670 nm, gave the transfer time of 8.3 ps, as compared to 0.7 ps for the wild-type complex. All the observed trends of the transfer time are in qualitative agreement with what one would expect based on Förster spectral overlap. However, quantitative Förster theory calculations of the transfer time based on the dipole–dipole interaction between B800 and nearby B850s failed to reproduce the observed lifetimes by almost an order of magnitude. Since the spectral overlap did describe the qualitative trend, it was suggested that the source of the discrepancy is the electronic coupling term (Herek *et al.*, 2000). It has been pointed out that the carotenoid molecule may contribute to the electronic coupling between B800 and B850 ((Sundstrom, Pullerits and vanGrondelle, 1999) and references therein). Alternatively, the nondiagonal and/or diagonal (Sumi, 1999) electron–phonon coupling may facilitate efficient excitation transfer to optically forbidden exciton levels. In the spirit of the same ideas, a modified Förster theory adapted for transfer to the collective exciton states with spectral inhomogeneity has been used for describing B800 to B850 transfer, apparently leading to quantitative agreement between theory and experiment (Scholes and Fleming, 2000).

5.6
Delocalized Excitons in Photosynthetic Light Harvesting

The B850 ring of LH2 (Figure 5.1a) forms a densely packed excitonically coupled aggregate. Shortly after the structure of the LH2 became available, the question of the extent of exciton delocalization in B850 became a hot research subject. Different experimental techniques and theoretical methods led to diverging and sometimes even contradicting conclusions. On the basis of nonlinear absorption experiments (Leupold *et al.*, 1996) it was concluded that the excitation is delocalized over almost the whole B850 ring whereas analyses of the transient absorption spectra suggested quite limited exciton delocalization on the picosecond timescale – about 4 BChl molecules (Pullerits, Chachisvilis and Sundstrom, 1996). Many of the following studies supported one or the other point of view (Meier, Chernyak and Mukamel, 1997; Monshouwer *et al.*, 1997; Chachisvilis *et al.*, 1997). The apparent controversy was resolved by considering that the exciton, and thereby also exciton delocalization, is time-dependent (Dahlbom *et al.*, 2001). Furthermore, different definitions of exciton delocalization length led to rather different numerical values for the quantity. We showed that at the moment of excitation certain measures of exciton delocalization indeed gave numerical values suggesting full-ring excitons. After a few hundred femtoseconds most of the measures gave the value ∼4 BChls (Dahlbom *et al.*, 2001). Figure 5.5 illustrates calculated time dependencies of exciton delocalization in B850 for several different definitions of the delocalization. The calculated results are correlated to various types of measurements of exciton delocalization.

At high light intensities it may happen that two or more excitations are simultaneously present in a set of molecules exchanging excitation, like B850. In this

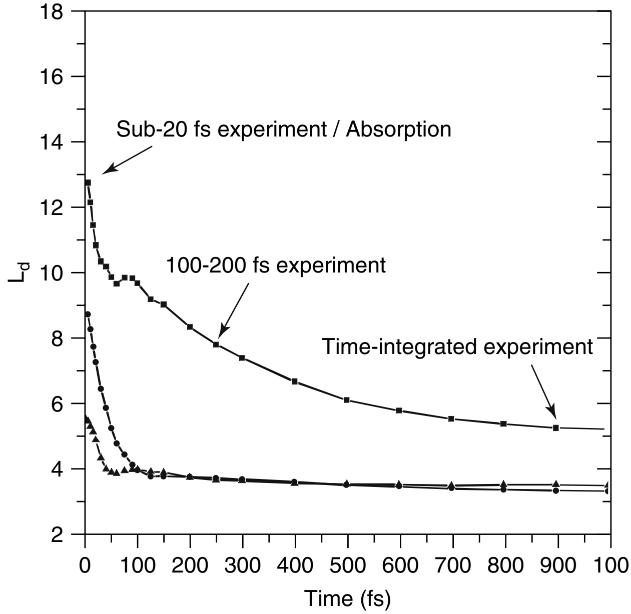

Fig. 5.5 Calculated time dependencies of exciton delocalization, L_d (number of BChl molecules over which exciton is delocalized), in B850 for several different definitions of the delocalization. The arrows indicate what would be the observed delocalization for different types of experiments.

case excitation annihilation can take place (Mauzerall, 1976; Denhollander, Bakker and vanGrondelle, 1983). The annihilation process is usually described as excitation transfer to an already excited molecule, where it produces a higher (doubly) excited electronic state. By very fast internal conversion the molecule relaxes to the lowest excited molecular state and one excitation is lost. Simultaneous analysis of excitation annihilation dynamics and transient absorption anisotropy decay in well-separated rings of LH2 was recently used for obtaining detailed information about excited state properties and dynamics in a B850 ring (Trinkunas *et al.*, 2001). It was confirmed that excitons in B850 are delocalized over 3–4 BChls.

5.7
Efficient Antenna–RC Coupling: Long Distance versus Short Distance

The last step in excitation transfer is transfer from the antenna to the special pair of the RC (energy trapping). Already early studies indicated that the trapping by the RC is slow (Visscher *et al.*, 1989). The rate of antenna to RC transfer was first determined by Timpmann *et al.* (1993) to be 30–40 ps, that is demonstrating that the final antenna–RC energy transfer step is the slowest and rate limiting step in the overall energy converting process. The trapping of excitation energy by the photosynthetic RC has often been discussed in terms of a trap-limited or diffusion-limited process, implying that the rate limiting process is charge separation in the RC, or the energy diffusion process through the antenna, respectively. The realization that the antenna to RC energy transfer step is rate limiting, was termed *transfer-to-trap-limited* (vanGrondelle *et al.*, 1994; Timpmann *et al.*, 1993). The structure of the purple bacterial LH1–RC complex (Figure 5.1a) explains the result, the distance between the RC and the LH1 BChls is the longest distance, which by virtue of the strong distance dependence (sixth power) of the energy transfer rate will be the slowest step. The functional importance of this large LH1–RC distance is that it prevents photo-oxidation of antenna BChls, and concomitant excited state quenching in the antenna, by the oxidized special pair of the RC.

An issue sometimes raised in the literature is the role of collective excited states, excitons, in photosynthetic light harvesting. Formation of collective excited states through interchromophore interaction leads to increased dipole strength of the collective state as compared to the monomeric chromophore. Energy transfer involving collective excited states will therefore be faster than energy transfer involving monomeric pigments under otherwise identical conditions. Since the last energy transfer step to the RC is the slowest, this step is most influenced by collective excitations. Thus, the overall trapping and thereby efficiency of photosynthesis is significantly improved by exciton formation in LH1.

Characteristic times of the different energy transfer steps discussed above are highlighted in the figure of the purple bacterial PSU in Figure 5.1a. Energy transfer between neighboring BChl molecules within the LH1 or LH2 pigment–protein complexes occurs on the ~0.1 to 1 ps time scale, whereas transfer between these complexes takes ~5 ps. The final energy transfer step from the LH1 ring to the special pair in the RC is characterized by the slowest energy transfer, ~35 ps. This results in efficient transfer of energy from any point in the network of antenna pigments to the RC, such that energy is stored in the RC within 50–100 ps after light absorption with an overall quantum efficiency approaching unity. Other pigment systems of other photosynthetic organisms, despite being composed of different pigments and having very different organization, show similar time scales of the energy transfer processes (vanGrondelle *et al.*, 1994; van Amerongen and van Grondelle, 2001; van Grondelle and Novoderezhkin, 2006; Croce *et al.*, 2000, 2003; Karapetyan *et al.*, 1999).

5.8
Carotenoid Molecules in Photosynthesis – Their Spectroscopy

Carotenoids are, along with chlorophylls, the most abundant pigments found in nature. They are present in most organisms including humans, but can be synthesized only by plants and microorganisms. While they are perhaps best known for their bright colors, they have well-documented multiple functions in nature: they serve as light-harvesting pigments in almost all photosynthetic organisms covering a region of the visible spectrum not accessible by (bacterio)chlorophylls and they protect against excessive light by quenching both singlet and triplet states of (B)Chls (van Amerongen and van Grondelle, 2001; Frank and Cogdell, 1993, 1996; Koyama *et al.*, 1996; Ritz *et al.*, 2000).

The diversity of carotenoid functions is unmatched by any other class of natural pigments. The functional variety is directly related to their unique spectroscopic properties resulting from the structure of the carotenoid molecule (Figure 5.6). The central pattern repeated in all carotenoids is a backbone consisting of alternating single and double carbon bonds that form a conjugated π-electron system responsible for most of the spectroscopic properties of carotenoids. An energy level scheme of a carotenoid molecule together with transitions, which will be used to describe the dynamics of excited states in the following sections, is depicted in Figure 5.7. The strong absorption of carotenoids (extinction coefficients of the order of 10^5) in the blue-green spectral region is caused by the strongly allowed S_0-S_2 transition. The S_0-S_2 transition of carotenoids usually exhibits a characteristic three-peak structure corresponding to the lowest three vibrational levels of the S_2 state. The energy of the S_0-S_2 transition decreases with the conjugation length (N) and can be

in the first approximation expressed as $E = A + B/N$, where the parameter A is the energy of the 0–0 vibrational band of the S_0–S_2 transition for an infinitely long carotenoid (Polivka and Sundstrom, 2004 and references therein). Besides the number of conjugated double bonds, the 0–0 energy is also affected by the structure of the carotenoid. For example, the nonplanarity of the conjugated C=C bond located at the β-ionylidene ring leads to a decrease of the effective conjugation length. This results in higher S_2 energy of β-carotene and zeaxanthin than for their linear counterpart lycopene, which also possesses 11 conjugated double bonds.

Longer carotenoids violate Kasha's rule as they exhibit emission from the S_2 state. The critical conjugation length for which the S_1 emission that dominates for shorter conjugation changes to S_2 emission is around eight conjugated C=C bonds. Studies of a series of open-chain carotenoids demonstrated that those with a conjugation length of eight exhibit dual emission from both the S_1 and S_2 states (Frank *et al.*, 2002). The S_2 emission constitutes almost a mirror image of the absorption spectrum with a Stokes shift of 150–300 cm^{-1}, almost independent on conjugation length for carotenoids with conjugation lengths 9–13 (Christensen *et al.*, 1999; Fujii *et al.*, 2001).

While the radiative lifetime of the S_2 state as calculated by the Strickler–Berg equation (Strickler and Berg, 1962) is in the range of nanoseconds, measured quantum yields of the S_2 emission of the order of 10^{-5} showed that internal conversion on the subpicosecond time scale governs the S_2 dynamics. Thus, information about the dynamics of the S_2 state relies solely on ultrafast time-resolved techniques. Application of such techniques to a number of carotenoids employed in photosynthesis established that the S_2 lifetime is in the range of 100–300 fs (Ricci *et al.*, 1996; Akimoto *et al.*, 1999, 2002) and dependent on both conjugation length and solvent parameters. The very short excited state lifetime of the carotenoid S_2 state implies that the properties of the S_1 state are crucial for understanding photophysics of carotenoids, in other words, much of the functions of carotenoids involving excited states will originate from the S_1 state. Because of the forbidden nature of the S_0–S_1 transition, knowledge about energetics and dynamics of this key excited state was until recently very limited. Since the theoretical prediction in 1972 of the $2A_g^-$ state being the lowest excited state in longer polyenes and carotenoids, it took more than 20 years until the energy of this state could be determined experimentally for longer carotenoids.

Much effort has gone into determining the energy of the dark S_1 state of naturally occurring carotenoids having conjugation lengths in the range 7–13. An indirect approach that has been used is to determine the S_1 energy of short carotenoids from their S_1 fluorescence and extrapolate to longer carotenoids. Progress in very sensitive fluorescence detection during the 1990s enabled direct measurement of the very weak S_1 fluorescence even from photosynthetic carotenoids with conjugation lengths 9–13. Raman spectroscopy is another method that has been employed in carotenoid research. Under the conditions of resonance Raman when the excitation light is in resonance with an electronic transition of the studied molecule, the intensities of the Raman lines are greatly enhanced. Thus, tuning the detection to the frequency of either C=C or C–C stretching modes and scanning the excitation light over a broad spectral range, a resonance Raman profile can be obtained. The high sensitivity of Raman line intensities to the resonance conditions enables detection of even dark states with very low transition dipole moments. Using this technique, the S_1 state energy of several carotenoids has been determined.

A different approach employing femtosecond time-resolved spectroscopy to locate the S_1 energy of carotenoids, based on the fact that the S_1–S_2 transition is symmetry allowed, emerged in 1999 (Polivka *et al.*, 1999). A femtosecond excitation pulse populates the lowest vibrational band of the well-characterized S_2 state to avoid contribution from vibrational relaxation within this state. The excited molecule then relaxes to the S_1 state on the time scale of 50–300 fs as described above. By scanning the wavelength of the probe pulse within the time window dictated by the lifetime of the S_1 state, the S_1–S_2 resonance can be found. Given the known spectral profile of the S_2 state and lifetime of the S_1 state, the S_1–S_2 transition must (i) reflect the spacing between the S_2 vibrational bands and (ii) decay with the S_1 lifetime. If these two conditions are fulfilled, the energies of the vibrational bands of the S_1–S_2 transition can be determined. The precise location of the carotenoid S_1 state can then be obtained, since its 0–0 spectral origin can be calculated from the spectral origins of the S_0–S_2 and S_1–S_2 transitions. Although this approach is quite straightforward, its application requires tunable femtosecond pulses in the 1–2 μm spectral range where the S_1–S_2 transition is expected. Along with the availability of laser sources generating such pulses in the late 1990s, this method became a powerful tool to study the properties of the S_1 state of carotenoids. Typical S_1–S_2 profiles of two carotenoids with different conjugation lengths are shown in Figure 5.8. The first application of this method was used to locate the S_1

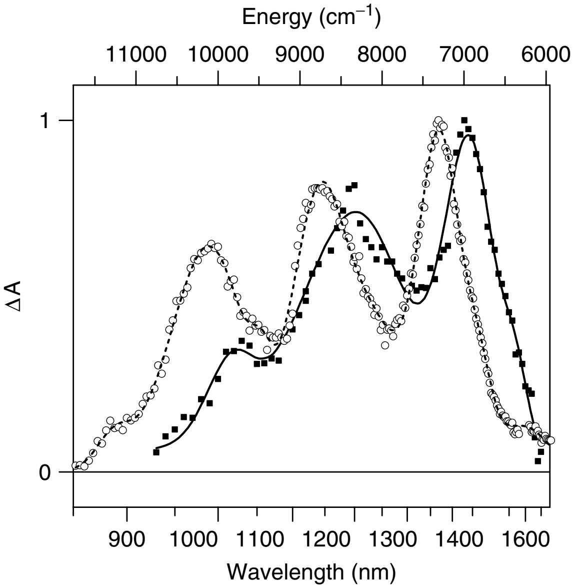

Fig. 5.8 S_1-S_2 transient absorption spectra of spheroidene in *n*-hexane (open circles) and violaxanthin in methanol (full squares) in the spectral region 850–1750 nm. From these spectra and the ground state absorption spectrum the energy of the forbidden lowest excited state (S_1) can be obtained (Polivka *et al.*, 1999).

energies of two carotenoids, violaxanthin and zeaxanthin, that participate in the xanthophyll cycle of higher plants, $14\,030 \pm 90\,\text{cm}^{-1}$ for zeaxanthin and $14\,470 \pm 90\,\text{cm}^{-1}$ for violaxanthin (Polivka *et al.*, 1999).

Comparing the various methods used to locate the S_1 energy of carotenoids, it is clear that all of these methods have their own advantages and disadvantages, and success of their application depends on the studied system. While fluorescence and resonance Raman methods are useful tools for measurements of the S_1 energy of shorter carotenoids in solution, their use is rather limited for carotenoids having more than 10 C=C bonds, since the signals become extremely weak, putting severe constraints on a reliable data analysis. On the other hand, the S_1-S_2 spectra are more reliable for longer carotenoids, since the longer carotenoids exhibit a larger S_1-S_2 energy gap, shifting the S_1-S_2 profile toward higher energies, thus making the detection easier. For carotenoids with $N \leq 9$, the 0–0 band of the S_1-S_2 transition can extend below $5000\,\text{cm}^{-1}$, where vibrational overtones originating from solvent may occur. Although higher vibrational bands of the S_1-S_2 transition can be used to obtain the S_1 energy, the precision is certainly lower in such a case. Despite these complications, the S_1-S_2 method is the only one providing information about both energy and lifetime of the S_1 state, which makes it very useful in establishing excited state properties.

5.9
Light Harvesting by Carotenoid Molecules

Chlorophyll and bacteriochlorophyll lack optical absorption in the blue-green part of the spectrum, while carotenoids have intense absorptions. Carotenoids therefore act as accessory light-harvesting pigments, but they have also many other important functions in photosynthesis. In addition to light harvesting, we will discuss their role in photoprotection. That carotenoids can transfer energy to Chls and BChls was known long before the X-ray structures were resolved. Initial suggestions regarding mechanisms and pathways of carotenoid–BChl energy transfer in LH2 and LH1 complexes proposed energy transfer via the S_1 state, because of extremely fast deactivation of the S_2 state. The forbidden nature of the S_1 state led to a suggestion that the Dexter electron exchange mechanism (Dexter, 1953) is active in this process (Cogdell and Frank, 1987). However, the first time-resolved experiments performed in the early 1990s showed that following the excitation of carotenoids the B850 Q_y state was populated in less than 200 fs, signaling that both the S_1 and S_2 states may be efficient donors in the carotenoid–BChl energy transfer process (Trautman *et al.*, 1990). Calculations of carotenoid–BChl energy transfer also led to the conclusion that both the S_1 and S_2 states can be active in energy transfer (Nagae *et al.*, 1993). A large number of time-resolved studies on various LH1 and LH2 complexes later showed that energy transfer occurs from both the S_1 and S_2 states of carotenoids to the Q_y and Q_x excited states of BChl (for more details see Polivka and Sundstrom, 2004). All the documented energy transfer pathways of an LH2 complex are summarized in Figure 5.9. Energy transfer from the optically excited carotenoid S_2 state was shown to occur in competition with the ultrafast S_2-S_1 internal conversion; transfer times varying between $\sim$50 and 150 fs, yielding energy transfer efficiencies for the S_2-Q_x channel of $\sim$50 to 60% have been reported. The mechanism of S_2 energy transfer was concluded to be of the Förster-type (Damjanovic, Ritz and Schulten, 1999), but contrary to the point dipole–point dipole interaction used in the Förster formula (Forster, 1946), full Coulombic interaction is usually used to calculate couplings between carotenoids and BChl. The reason for this is that the point-dipole description of interacting chromophores inherent in the traditional Förster mechanism fails for extended molecules at interaction distances comparable to or shorter than the size of

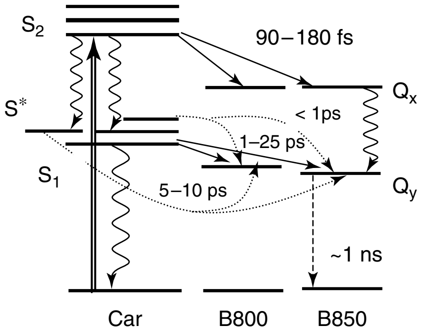

Fig. 5.9 Schematic energy level scheme for energy transfer from carotenoids to BChls in LH2. Major pathways are indicated with full arrows, while minor paths are dotted.

the involved molecules. The contribution of the electron-exchange (Dexter) energy transfer mechanism (Dexter, 1953) to S_2 energy transfer is negligible (Polivka and Sundstrom, 2004).

The energy level scheme of Figure 5.9 suggests that the carotenoid S_1 state must be higher in energy than the Q_y states of B800 and B850 BChls for efficient carotenoid–BChl transfer via the S_1 state. Before any carotenoid S_1 energy in a light-harvesting complex had been measured, estimates based on S_1 energies in solution indicated that carotenoids with $N \leq 10$ would have sufficiently high S_1 energies to efficiently transfer energy to both B800 and B850. By using several LH2 complexes having carotenoids of different conjugation lengths and comparing the S_1 lifetime of the carotenoids in solution and protein, this expectation was confirmed – carotenoids with $N \geq 11$ were shown to have very little S_1 energy transfer to BChl, while shorter carotenoids exhibited transfer efficiencies of 80–95%. The energetic requirement for efficient S_1-mediated energy transfer was finally demonstrated by direct measurement of carotenoid S_1 energies in light-harvesting complexes through recording of S_1–S_2 spectra (Polivka *et al.*, 2002a, 2002b). Both B800 and B850 were shown to accept energy from carotenoids, although B800 appears to be a somewhat more efficient acceptor. Calculations of carotenoid S_1–BChl energy transfer for several LH2 complexes showed that the observed S_1 transfer rates can be explained in terms of the same energy transfer mechanism as for the S_2 route. Although the very small transition dipole moment of the S_0–S_1 transition led initially to a suggestion that the Dexter mechanism had to be invoked, more detailed calculations later showed that the Dexter contribution is negligible and that higher-order Coulombic and polarization interactions dominate the S_1-mediated energy transfer (Scholes, Harcourt and Fleming, 1997).

5.10
Protection of the Photosynthetic Machinery (NPQ) – Quenching of Chlorophyll Excited States by Carotenoids

Quenching of various reactive excited states is probably the most important carotenoid function in photosynthesis. Carotenoids may quench both singlet and triplet (bacterio)chlorophyll excited states, as well as singlet oxygen. Here, we will only consider the quenching of Chl excited singlet states in the LHCII antenna complexes of green plants. Under certain conditions one of the carotenoid binding sites of LHCII can be occupied by zeaxanthin and this was suggested to trigger a structural change of the protein leading to quenching of Chl fluorescence (Crimi *et al.*, 2001), which is the origin of the photoprotective mechanism called *nonphotochemical quenching* (NPQ). This mechanism protects against damage caused by excessive photon flux by dissipating the energy thermally in PS2 (DemmigAdams and Adams, 1996; Horton, Ruban and Walters, 1996). It involves a cascade of processes triggered by high light conditions resulting in enzymatic conversion of violaxanthin to zeaxanthin by means of the xanthophyll cycle. Although a fundamental understanding of NPQ is still lacking, it is clear that one of the crucial components is a zeaxanthin-induced quenching of Chl-*a* excited states, as presence of this carotenoid reduces markedly the Chl-*a* fluorescence lifetime (Polivka *et al.*, 2002b; Richter *et al.*, 1999; Frank *et al.*, 2001). Several different mechanisms have been suggested for this quenching process. Frank *et al.* proposed the so-called "molecular gear shift mechanism" (Frank *et al.*, 1994) as a mechanism for NPQ. In the initial proposal based on S_1 energies estimated from the energy gap law, violaxanthin was supposed to have its S_1 energy above the Q_y transition of Chl-*a* serving as energy acceptor, while zeaxanthin had an S_1 energy sufficiently low to act as quencher of excited Chl-*a*. Then, exchange of violaxanthin to zeaxanthin by means of the xanthophyll cycle would enable increase of quencher concentration, explaining the mechanism of NPQ. Later, direct measurements of the S_1 energies in both solution and LHCII (Polivka *et al.*, 1999) challenged this mechanism, since the S_1 energies of both violaxanthin and zeaxanthin were shown to be below the Chl-*a* Q_y state. Nevertheless, although the initially proposed "molecular gear shift" would not work, the location of the zeaxanthin S_1 state below the Chl-*a* Q_y transition still allows direct quenching. Direct involvement of the zeaxanthin S_1 state in NPQ was also shown in a femtosecond transient absorption study of intact thylakoid membranes of *thaliana* (Ma *et al.*, 2003; Holt *et al.*, 2005). After excitation of either Chl-*b* or Chl-*a* by ~100 fs pulses, the zeaxanthin S_1 state was observed to be directly populated, signaling very fast energy transfer from Chl to zeaxanthin (and thus Chl excited state quenching). The formation of the zeaxanthin S_1 state was correlated to the presence of the PsbS protein that is known to be an essential part of NPQ (Li *et al.*, 2000), thus confirming the relation between population of the zeaxanthin S_1 state and NPQ. Further, time-resolved spectroscopy work (Holt *et al.*, 2005) and calculations (Ma *et al.*, 2003) indicated that the quenching mechanism could involve energy transfer from chlorophyll molecules to a chlorophyll–zeaxanthin heterodimer, which then undergoes charge separation and formation of a zeaxanthin$^+$–Chl$^-$ radical pair. Another hypothesis proposed that the essential function of zeaxanthin is to promote changes in structure and/or organization of the light-harvesting complexes that eventually lead to quenching conditions. One such mechanism involves a structural change facilitating a formation of Chl-*a* excitonic pairs, which than play a role of quenchers (Crofts and Yerkes, 1994). Clearly, additional work is required before the mechanism of NPQ is fully clarified.

5.11
Storing the Energy of Light – Photosynthetic Charge Separation

As already discussed above, excitation energy captured by the antenna is transferred to the pigments of the RC where a sequence of ultrafast electron transfer steps convert the excited state energy in the antenna to a transmembrane potential. The core of the RC is made up of two homologous membrane proteins, called L and M, while a third polypeptide, H, covers the cytosolic surface (Deisenhofer *et al.*, 1985). Both L and M possess five membrane-crossing helices forming a cage around the four BChls, two bacteriopheophytins and two quinones noncovalently bound to the RC (Figure 5.10). With respect to both the proteins and the cofactors, the RC shows

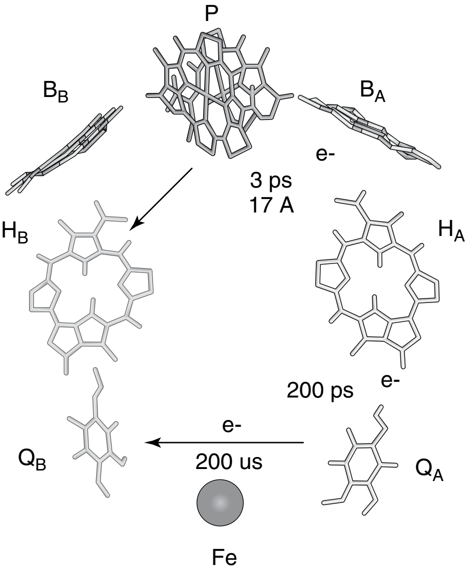

Fig. 5.10 Structure of the bacterial RC, showing the cofactors. P – special pair; B_A and B_B – accessory monomeric chlorophylls; H_A and H_B – pheophytins; Q_A and Q_B – quinines.

a remarkable C_2-symmetry with the symmetry axis running through the middle of the centrally located ‘‘special pair’’ (P) of BChl molecules and the nonheme iron. The pigments are arranged in two branches labeled A and B, but surprisingly, electron transfer occurs only along the A (or ‘‘active’’) branch. Following excitation of the special pair (transfer of excitation energy from the antenna), charge separation occurs within a few picoseconds to yield the oxidized special pair, P^+, and a reduced bacteriopheophytin, $H_A{}^-$. The electron then hops to a quinone molecule, Q_A, in about 200 ps, and on to a second quinone Q_B in 100 μs. P^+ is restored to neutrality by electron transfer from a cytochrome. This sequence of reactions is repeated after the absorption of a second photon, and then the doubly reduced Q_B molecule leaves the RC as Q_BH_2 and an electrochemical gradient has been created across the photosynthetic membrane in which the RC is positioned.

The understanding that primary charge separation occurs within ~3 ps with the formation of P^+ and $H_A{}^-$ was a result of subpicosecond absorption measurements in the mid-1980s. These results generated much discussion on the nature of the electron transfer between the special pair and the bacteriopheophytin. Taking into account that the edge-to-edge distance between P and H_A is 11 Å, a simple model predicted the time-constant for direct electron transfer to be approximately 1 ns. From the crystal structure of the RC it was apparent that the monomeric BChl (B_A) is ideally situated to be an intermediate in the electron transfer pathway $P \rightarrow B_A \rightarrow H_A$. However, in the time-resolved measurements there were no known spectral changes that could be unambigously interpreted as a transient population of a $B_A{}^-$ species. To solve these difficulties, a mechanism was proposed that included B_A as a virtual intermediate. In this so-called superexchange mechanism it is assumed that the coupling between P and H_A is provided by B_A, but that the radical pair $P^+B_A^-$ is never significantly populated since it is far above the excited state of P (P*) in free energy. Today, most workers in the field support the proposal originally made by Shuvalov and coworkers (Chekalin *et al.*, 1987) and later verified by Zinth and coworkers (Holzapfel *et al.*, 1990; Arlt *et al.*, 1993) that B_A is transiently observable as an electron transfer intermediate, with the transfer time of the electron away from P* (3–4 ps) almost three times slower than the transfer away to H_A (about 1 ps). An important confirmation that $P^+B_A^-$ is indeed a detectable intermediate in charge separation came from the discovery of the B_A^- anion absorption band around 1020 nm.

In spite of the obvious symmetry of the RC, the electron transfer essentially occurs only along the A-branch. Estimates of the coupling strengths along both paths do indeed favor the active branch, but not in the experimentally observed 200 : 1 ratio. One conspicuous feature in the RC structure is a tyrosine residue (TyrM208 in *Rhodopseudomonas viridis*, TyrM210 in *sphaeroides*) strategically positioned between the cofactors in the active branch, while the symmetry-related residue in the inactive branch is a phenylalanine (PheL181). A variety of groups studied RCs with mutations introduced at these positions and they observed dramatic changes in the rate of charge separation (e.g. Jia *et al.*, 1993; Visschers *et al.*, 1999). For most mutations the rate slowed down, sometimes dramatically. Surprisingly, for a mutation that restored the symmetry with tyrosines at positions L181 and M208 the rate increased slightly. These observations were explained within the framework of the Marcus theory (Marcus and Sutin, 1985) for electron transfer, and ascribed to changes in the free energy of the initial radical pair due to the mutation. The free energy dependence of the rate suggested that any change in the protein structure during electron transfer (the reorganization energy) is very small. Nevertheless, in none of the mutants was electron transfer observed along the inactive branch. Other types of mutants were also generated – mutants in which H-bonds of the protein were modified around P produced dramatic changes in its redox potential, again without affecting the asymmetry of electron transfer. In a double mutant with H_A replaced by a bacteriochlorophyll and $P^+B_A^-$ upshifted in free energy, Holten and coworkers detected a measurable amount of $P^+H_B^-$ (Kirmaier *et al.*, 1991). This suggests that the free energy of the charge-separated states controls the asymmetry of the electron transfer, rather than the differences in electronic coupling.

Following excitation of bacterial RCs with femtosecond excitation pulses, oscillatory patterns have been observed in the transient absorption changes (Vos *et al.*, 1993) and spontaneous emission (Stanley and Boxer, 1995). Typically these phenomena are explained by the generation of coherent wavepackets on the excited state surface due to the broad spectral bandwidth of the short excitation pulse. The Fourier transform spectrum of these oscillations indicated dominant modes at 15 and 77 cm^{-1} and a smaller contribution from a mode at 90–100 cm^{-1}. The modes are consistent with the ground state resonance Raman spectrum of P and possibly result from the protein or are weak low-frequency modes from the BChls that are enhanced in the special pair configuration. Observation of these oscillatory signals questions the conventional assumption that vibrational dephasing and relaxation occur on a time scale that is much shorter than the electron transfer, and therefore challenges conventional theory used for describing the primary electron transfer steps in RCs.

The charge transfer processes described above account for the main function of the RC converting the light energy delivered to the special pair from the light-harvesting antenna into a stable charge separation across the photosynthetic membrane. All of the pigments of the RC can of course directly absorb light as well; however, due to their relatively low concentration as compared to LH pigments, this contribution plays no practical role for the total light absorption of the PSU. Nonetheless, for characterizing the various pathways of energy and electron flow within the RC it is of interest to study these processes. It is generally assumed that excitation of all other pigments than P results in ultrafast energy transfer to P (Breton *et al.*, 1986), followed by the conventional charge separation to form the $P^{+}H_{A}^{-}$ radical pair. Indeed, a variety of ultrafast measurements in which B_A and B_B were selectively excited demonstrated that energy transfer to P occurs within a few hundred femtoseconds (Jonas *et al.*, 1996). It has also been demonstrated that direct excitation of the accessory B_A pigment leads to a charge separation $P^{+}H_{A}^{-}$ within ~200 fs, without the involvement of P* (van Brederode *et al.*, 1999). In the PS2 RC of green plants, the charge separation starting at the accessory chlorophyll was shown to be functionally important. From the first purification work on the PS2 RC, showing strong homology between the bacterial and PS2 RCs, it was speculated that the operation of the two RCs would be similar. However, the spectroscopic similarity of all chromophores in the PS2 RC led to a proposal that charge separation in the PS2 RC follows the minor pathway of charge transfer demonstrated for bacterial RCs and starts at the accessory chlorophyll. Data from spectroscopic and time-resolved measurements combined with theoretical modeling indeed now strongly suggest that the primary charge separation occurs between the accessory chlorophyll in the D_1 subunit and the pheophytin in the same subunit. Only by a secondary electron transfer step is the radical pair involving the special pair P680 and the pheophytin, $P680^{+}$-H^{-}, formed (Groot *et al.*, 2005; Novoderezhkin *et al.*, 2005).

Acknowledgments

I wish to thank all my coworkers at the Department of Chemical Physics, Lund University, for fruitful discussions. I thank prof. R. van Grondelle for the spectrum of Figure 5.3a.

6.1
Introduction

Optical tweezers are a unique tool providing the ability to manipulate specimen with nanometer precision just by the use of light. With proper detection equipment, optical tweezers can also be used to measure the forces acting on, or by, a given micro- or nanoscale system. These are distances and forces typically present in biological systems at the macromolecular level. Therefore, optical tweezers have mediated new exciting discoveries within the field of bioscience. With proper chosen wavelength and intensity of the trapping laser light, optical tweezers can nearly nondestructively or noninvasively trap living microorganisms such as virus, bacteria, or eucaryotic cells. Besides, optical tweezers are the only nanotool that can measure forces on and manipulate naturally occurring objects, as, for example, organelles, inside living cells without destructively perturbing the cell wall.

Though the development of optical tweezers started only in the 1970s, the fact that light can exert force on particles has been known for centuries. Johannes Kepler proposed that radiation pressure from the sun is responsible for the tail of comets always pointing away from the sun. The basic physical principle behind this postulate was put into a theoretically consistent framework by J.C. Maxwell, proving that momentum is transferred when light interacts with an object.

With the invention of the laser, a highly collimated and very powerful source of light became available. This intense light source found use in the manipulation of atoms and molecules. In 1970, Arthur Ashkin made the first version of an optical trap; it was made by two counter propagating laser beams, and with this setup, dielectric particles could be optically trapped in liquids and air (Ashkin, 1970). Trapping was mediated by the counteracting radiation pressures from two opposing laser beams. In 1986, the development of optical tweezers took another major step forward – Arthur Ashkin demonstrated that using a green argon ion laser (Ashkin *et al.*, 1986) dielectric particles could be trapped with a single, highly focused, laser beam. Adding to the potential of the technique was also the fact that he was also able to trap living microorganisms such as yeast, bacteria, and virus (Ashkin, Dziedzic and Yamane, 1987). And the microorganisms did not appear too damaged by the laser light. In contrast to the previous trap based on radiation pressure, the trapping

ISBN: 978-3-527-40702-6

capabilities of the tightly focused single laser beam are caused by the spatial gradient force, which always pulls dielectric objects toward the region of highest intensity. By tightly focusing a laser beam he found that the gradient force of a single beam could overcome the scattering force by the same beam, hence leading to a stable three-dimensional trapping condition.

Current technical developments have evolved the technique of optical tweezers to a stage where they can be used to measure subnanometer distances and forces as feeble as femto-Newton. In the following, there is first a description of the principles of optical trapping, of how to measure forces and distances, the basic equipment, and concerns. Then focus is on the applicability of the technique, on which objects can be trapped, and on some of the very exciting biological applications that have arisen, most noteworthy among them being the unraveling of the function of a single biological molecule.

6.2
Basic Principles

The functioning of an optical trap relies on the fact that photons carry momentum, $|\mathbf{p}| = h/\lambda$, λ being the wavelength of the light and h Planck's constant. Let $\mathbf{S}$ be the Poynting vector describing the light from the laser. Upon encounter with an object, the light interacts with the object and the object feels a force, $\mathbf{F}$, due to refraction and reflection of the light by the object:

$$\mathbf{F} = \frac{n}{c}\int (\mathbf{S}_{\text{in}} - \mathbf{S}_{\text{out}})\,\mathrm{d}A \qquad (1)$$

where $\mathrm{d}A$ is the projected area of the object, n the index of refraction, and c the speed of light. This means that light exerts force on all objects that reflect or refract light. The radiation force can be decomposed in components arising from refraction and reflection, respectively. The component arising from reflection pushes the object along the propagating direction of the laser light and is known as the *scattering force*. The component arising from the refraction is termed the *gradient force*, and this force pulls an object with refractive index higher than the surrounding media toward the most intense region of the laser beam.

In principle, one can use Eq. (1) to calculate the force acting on the particle. However, in practice, this is either very difficult or not possible. To simplify the treatment of how light can trap particles, two limiting cases can be considered, namely the Rayleigh regime, where the trapped object, with typical linear dimension d is considerably smaller than λ and the Mie regime, where the d is considerably bigger than λ and where the ordinary ray-optics picture can be applied. In any case, to achieve successful trapping, the gradient force must be larger than the scattering forces.

6.2.1
Rayleigh Regime, $d \ll \lambda$

As the size of the object is considerably smaller than λ, it can be described as a point dipole. Hence, the incoming electrical field, $\mathbf{E}$, induces a dipole $\mathbf{d}$, in the dielectric object,

$$\mathbf{d} = \alpha\mathbf{E} \qquad (2)$$

where α is the polarizability of the object. The potential, U, describing the interaction between the dipole and the electromagnetic field is given by

$$U = -\mathbf{d} \cdot \mathbf{E} \tag{3}$$

This potential gives rise to a force,

$$\mathbf{F}_{\text{grad}} = -\nabla U = \alpha \nabla E^2 \tag{4}$$

which is denoted the gradient force and is proportional to the gradient of the intensity profile.

6.2.2
Mie Regime, $d \gg \lambda$

This is the case where the trapped object is considerably larger than λ, a scenario which is depicted in Figures 6.1 and 6.2. In this regime, Eq. (1) is fairly easily applicable. Consider a situation as depicted in Figure 6.1 where a laser beam is incident from above with an intensity profile that is increasing toward the center of the beam (e.g. a Gaussian intensity profile). Let a bead having an index of refraction larger than the index of refraction of the surrounding media be slightly displaced to the left with respect to the center of the beam. The most intense part of the laser beam, denoted "1" in Figure 6.1, will be refracted according to Snells law upon interaction with the bead. Comparing the direction of part "1" of the laser beam before and after encounter with the bead, it is clear that it has changed direction and hence momentum. Momentum must be conserved. Hence, the bead experiences an equally sized but oppositely directed change of momentum, $\mathbf{P}_{1,\text{bead}}$. Likewise, the momentum of the dimmer part "2" of the laser beam undergoes a change upon encounter with the bead. This gives rise to an equal in size, but opposite in direction, change of momentum of the bead, $\mathbf{P}_{2,\text{bead}}$. The sum of these two contributions is

$$\mathbf{P}_{\text{tot,bead}} = \mathbf{P}_{1,\text{bead}} + \mathbf{P}_{2,\text{bead}} \tag{5}$$

The total effect is that the bead is pushed toward the center of the laser beam. Integrating this argument over the entire laser profile gives a similar result, and hence, explains trapping in a direction orthogonal to the propagational direction of the laser light.

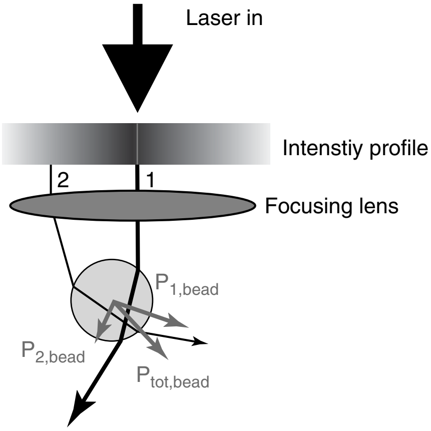

Fig. 6.1 Schematic drawing of the principle behind optical trapping in a direction orthogonal to the propagating laser light in the regime where ray optics apply.

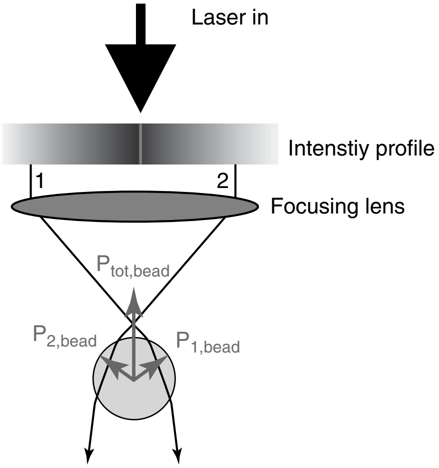

Fig. 6.2 Schematic drawing of the principle behind optical trapping in a direction parallel to the propagating laser light in the regime where ray optics apply.

To understand optical trapping in the parallel direction, consider a scenario as depicted in Figure 6.2. The laser beam has an intensity profile as in the case considered in Figure 6.1, but now it is important that the laser light passes through a focusing lens before encountering the bead. Let the bead be displaced slightly below the focus of the lens and consider two parts of the laser beam, parts "1" and "2," originating from opposite sides of the laser beam but carrying equal intensity. Again, parts "1" and "2" of the laser beam will experience a change in momentum upon passing the bead. Correspondingly, the bead experiences changes in momentum, $\mathbf{P}_{1,\text{bead}}$ and $\mathbf{P}_{2,\text{bead}}$, which are equal in size but opposite in direction to the changes of rays "1" and "2." The total contribution $\mathbf{P}_{\text{tot,bead}}$ will be directed upward the horizontal components canceling. Integrating this argument over the entire laser profile gives a similar result, and hence, explains trapping in a direction parallel to the propagational direction of the laser light.

6.2.3
Intermediate Regime, $d \simeq \lambda$

In this regime, the size of the trapped particle is on the same order as the wavelength of the trapping laser light. In fact, this is the situation most commonly encountered, and where an optical trap appears most efficient. Calculating the forces in this regime is difficult, mostly because how to apply Maxwell's equations is not trivial in a situation where the size and geometry of the object cannot be ignored. Recently, A. Rohrbach carried through a theoretical calculation based on electromagnetic force density, the so-called two-component approach (Jackson, 1975), to find the gradient and scattering forces by solving Eq. (1) (Rohrbach, 2005). The result was impressively close to experimental observations.

6.2.4
Finding the Forces

To find the forces exerted by an optical trap, consider a coordinate system where *x* and *y* are perpendicular to the direction of propagation of the laser, which is determined *z*. The three coordinates of the bead are uncorrelated, and the equation of motion for each of them is the same, but with different parameter values. Therefore, we can consider the motion in one dimension, for example in the *x* coordinate, only. The optical trap is assumed to exert a harmonic force, $\mathbf{F}_{\text{trap}}$, on a trapped object:

$$\mathbf{F}_{\text{trap}} = -\kappa \mathbf{x} \tag{6}$$

where κ denotes the spring constant of the optical trap, $\mathbf{x}$ is the deviation from the equilibrium position (center of trap), and the minus sign is due to the fact that the force always acts so as to push the object toward the center, opposite to the displacement, $\mathbf{x}$. As can be seen from the position the histogram shown in Figure 6.3, a harmonic potential is a reasonable approximation. The full line in Figure 6.3 is a Gaussian fit to the position data, and the inset shows the same but using a logarithmic ordinate axis.

As it is cumbersome, or maybe even impossible, in practice to theoretically calculate the forces exerted by optical tweezers, a far more reliable and easy method is to perform a force calibration. This can be done in several ways, of which the two most common procedures are mentioned here, namely the "Stokes drag calibration" and the "Brownian motion calibration."

6.2.4.1 Stokes Drag Calibration

Let a bead with a size well known in an aqueous chamber be held by an optical trap. By moving the trap with respect to

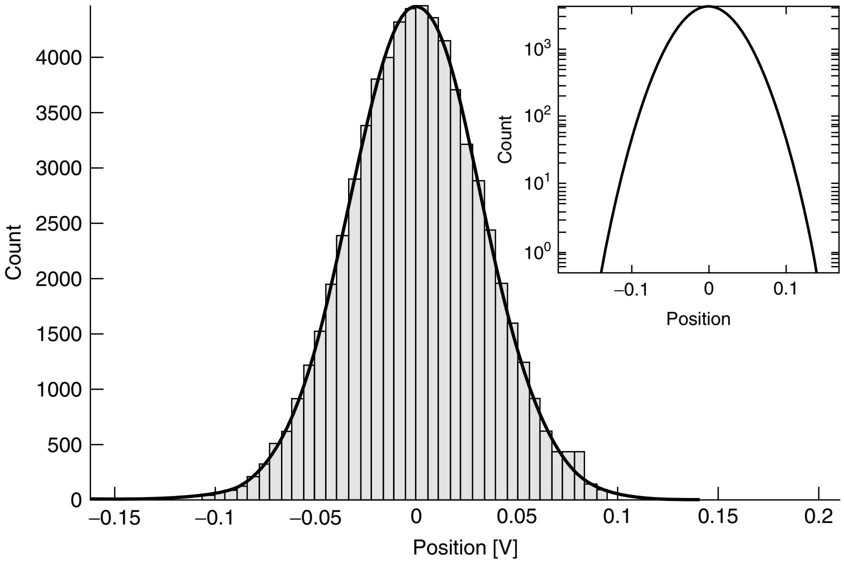

Fig. 6.3 Histogram of positions visited by a 2-µm bead held in an optical trap. The positions are measured by a photodiode in units of volts and can be converted to meters by multiplying by a conversion factor of 1.5×10^{-7} mV^{-1}. The standard deviation of the histogram is 0.03 V corresponding to ~5 nm. The full line is a fit by a Gaussian function to the data, and the inset shows the same but on semilogarithmic axes.

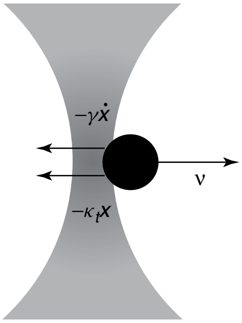

Fig. 6.4 Schematic drawing of velocity, v, of bead with respect to fluid and of the forces $\mathbf{F}_{\text{drag}} = -\gamma\dot{x}$ and $\mathbf{F}_{\text{trap}} = -\kappa_t x$ acting on an optically trapped bead.

the chamber with a constant velocity, one can exert a drag force, $\mathbf{F}_{\text{drag}}$, on the bead

$$\mathbf{F}_{\text{drag}} = -\gamma \boldsymbol{v}, \quad \gamma = 3\pi\eta d \tag{7}$$

where γ is the friction coefficient given by Stokes law, d the diameter of the bead, η the viscosity of the surrounding liquid, and $\boldsymbol{v} = \dot{x}$ the velocity of the surrounding media with respect to the bead. The minus sign shows that $\mathbf{F}_{\text{drag}}$ always points oppositely to the velocity vector, $\boldsymbol{v}$, as depicted in Figure 6.4. If $\boldsymbol{v}$ is kept constant, the bead will find a new equilibrium position, x_{new}. By measuring x_{new} and $\boldsymbol{v}$ and equating Eqs (7) and (6), the spring constant, κ characterizing the optical trap can be found.

By increasing $\boldsymbol{v}$ until the bead escapes the trap, a method known as *escape calibration*, the maximum force applicable by the optical trap can be found by using Eq. (7).

6.2.4.2 Brownian Motion Calibration

A precise and commonly used method to describe the forces exerted by optical tweezers utilizes the Brownian motion of the particle in the trap. This method requires a fast detection system (with respect to the relaxation time scales) that can determine the positions of the bead as a function of time.

To find the equation of motion of the particle, all forces acting on the particle must be considered. These are the harmonic force exerted by the optical trap, Eq. (6), the frictional forces exerted by the surrounding liquid, Eq. (7), and the bead is subject to a stochastic force $\mathcal{F}(\mathbf{T}, \mathbf{t})$ because of the Brownian motion of the surrounding liquid at temperature T and time t. $\mathcal{F}(\mathbf{T}, \mathbf{t})$ is assumed to be white noise with an average value of zero and a constant value of the power spectrum

$$|\tilde{F}(f)|^2 = 4\gamma k_B T \tag{8}$$

where k_B is the Boltzmann constant.

Since the mass of the bead is very small, and likewise the velocities, the Reynolds number describing the situation is very low, and the inertial term, $m\mathbf{a}$ (m is mass $\mathbf{a} = \ddot{x}$ is acceleration) is significantly smaller than the other forces mentioned. Hence, Newton's second law gives the equation of motion:

$$m\mathbf{a} = -\kappa\mathbf{x} - \gamma\boldsymbol{v} + \mathcal{F}(\mathbf{T}, \mathbf{t}) \simeq 0 \tag{9}$$

Upon Fourier transformation of Eq. (9), one obtains

$$2\pi\gamma(f_c - \mathrm{i}f)\tilde{x}(f) = \tilde{F}(f) \tag{10}$$

where the corner frequency f_c is given by

$$f_c = \frac{\kappa}{2\pi\gamma} \tag{11}$$

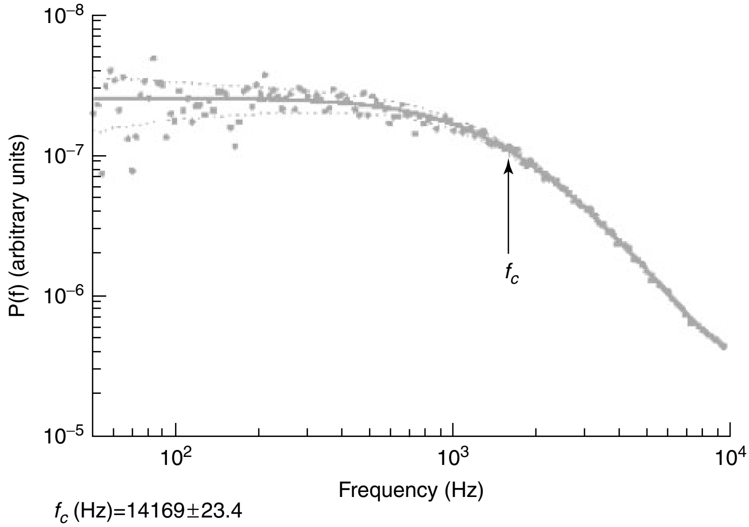

Fig. 6.5 Power spectrum. Fitting of data is performed by the procedures described in Hansen *et al.*, (2006).

Hence, the power spectrum, $S_x \equiv \langle |\tilde{x}(f)|^2 \rangle$, for the position x can be calculated as in Gittes and Schmidt (1998)

$$S_x = \frac{k_B T}{\pi^2 \gamma (f_c^2 + f^2)} \tag{12}$$

By plotting the positional power spectrum and fitting Eq. (11) to the data (as shown in Figure 6.5), one can obtain f_c for the data depicted in Figure 6.5, $f_c = 1417 \pm 23$ Hz. f_c separates two regimes from each other, namely the low-frequency regime, corresponding to large bead excursions limited in space by the trapping potential, thus resulting in a flat power spectrum, and the high-frequency regime, corresponding to small excursions, where the bead performs a simple Brownian motion inside the optical trap, this being characterized by a slop of -2 in the power spectrum. With γ known, for example, from Eq. (7), κ can be determined from Eq. (11). If x is measured and κ is known, then the force exerted by the optical trap is easily found, using Eq. (6).

In a harmonic potential, the equipartition theorem gives

$$\sigma^2 = \frac{k_B T}{\kappa} \tag{13}$$

With κ known from Eq. (11), σ (measured in meters), describing the standard deviation of the Gaussian position distribution as shown in Figure 6.3, can be found.

6.2.5
Proximity to Surfaces

The friction coefficient, γ is only well described by Stokes law (Eq. (7)) if surfaces are far away. However, often the geometry of a given experiment is such that the trapped object is close to a surface. In such cases, the friction coefficient is different, typically larger than that given by Stokes law. With proper detection, either using photodiodes or enhanced video microscopy, one can find the motion of a trapped particle in three dimensions. The corrections to γ depend on the direction of motion with respect to the surface. If one considers motion parallel to a surface (x or y directions with the coordinate system employed in previous sections), then the correctional factor, $k(h)$, to Stokes law given by Faxen's law conveniently formulated in Stout and Webb (1998):

$$k_{\text{parallel}}(h) = \left(1 - \frac{9}{16}\left(\frac{r}{h+r}\right) + \frac{1}{8}\left(\frac{r}{r+h}\right)^3 - \frac{45}{256}\left(\frac{r}{h+r}\right)^4 - \frac{1}{16}\left(\frac{r}{h+r}\right)^5\right)^{-1} \quad (14)$$

Here, h is the distance from the surface of the bead to the other surface, and r is the radius of the bead. Equation (14) is valid for $(h/r) > 0.02$.

The correction to diffusional motion in a direction normal to the surface is given by Brenner (1961):

$$k_{\text{normal}}(h) = \frac{4}{3}\sinh(\zeta) \times \sum_{n=1}^{\text{inf}} \frac{n(n+1)}{(2n-1)(2n+3)}\Omega(n,\zeta) \quad (15)$$

where

$$\Omega(n,\zeta) = \frac{2\sinh[(2n+1)\zeta] + (2n+1)\sinh(2\zeta)}{4\sinh^2[(n+\frac{1}{2})\zeta] - (2n+1)^2\sinh^2(\zeta)} - 1 \quad (16)$$

and

$$\zeta = \cosh^{-1}\left(1 + \frac{h}{r}\right) \quad (17)$$

The diffusion constant, D, is found as

$$D = \frac{k_B T}{3\pi\eta d k(h)} \quad (18)$$

The evolution of D in directions parallel to and normal to a surface is shown in Figure 6.6.

6.3
Equipment

To make optical tweezers on the basis of a single laser beam, in principle, one only needs laser light with a gradient in the intensity profile and a tightly focusing lens, that is, a lens with a high numerical aperture. To make an optical trap on the basis of the scattering forces from two counter propagating laser beams, the lenses directing the laser beams need not have a high numerical aperture.

For practical reasons and user friendliness, most labs find it useful to implement the tweezers in a microscope, typically an inverted microscope. Figure 6.7 shows a typical setup for optical tweezers.

The light emitted from the laser is expanded to a diameter, where it slightly overfills the back aperture of the objective. Then it passes through a variable attenuator, for example, consisting of a $\lambda/2$ plate and a polarizing beam splitter cube. The part of the laser light which is transmitted by the beam splitter cube is stirred into a microscope (the graey region on Figure 6.7) by means of a couple of mirrors. The orthogonally polarized part of the beam that is reflected by the beam splitter cube is often used as a second trap in the sample. Before entering the microscope, the beam passes through a telescope consisting of two lenses, one of these movable;

this allows translation of the focus of the laser inside the sample. Using a dichroic mirror, light is passed on to a microscope objective, which performs a tight focusing of the laser light, hence creating the optical trap. The sample is typically mounted on a piezo translational stage.

The detection can be done in different ways, one of the two most commonly applied methods is by means of a CCD camera, the images of which are afterward analyzed, for example, by single particle-tracking routines. The other method is by using photodiodes, most often a quadrant photodiode or a position-sensitive diode. The diode can be placed such that the forward-scattered laser light collected by the condenser after having passed the sample is imaged onto the diode. Or the diode can be placed such that it uses the backward-scattered light from the sample. In a photodiode, the voltage across an active area is proportional to the number of photons hitting the diode. If the laser beam is centered with respect to a quadrant photo diode, then a trapped object will cast a shadow, create an interference pattern on the diode. The x or y positions of the trapped object is found by subtracting the signal of one half of the quadrant photodiode from the signal of the other half (as sketched in Figure 6.7). The z position of the trapped object is proportional to the total signal on the photodiode. Hence, by using a photodiode, one can obtain three-dimensional information about the positions visited by the trapped object with nanometer precision. Compared to the CCD camera, photodiodes have the advantage of a faster acquisition rate, furthermore, data analysis requires far less computational efforts than image processing.

The recorded signal, stemming from a photo diode, gives the positions x, y, and z of the bead in volts. However, it is desirable to know the position of the trapped object in spatial units. Therefore, it is necessary to find the conversion factor A, translating the recorded signal in volts, to a position in meters. From a histogram of the positions measured in volts, as shown in Figure 6.3, the variance σ_V^2 (subscript V to indicate measured in volts) can be determined

$$\sigma_V^2 = \langle x_V^2 \rangle - \langle x_V \rangle^2 \tag{19}$$

From the powerspectral analysis as outlined in Section 6.2.4.2, one can find σ measured in meters using Eq. (13). By comparing the value for σ measured in volts to the value measured in meters, the desired conversion factor can be found:

$$A = \frac{\sigma}{\sigma_V} \tag{20}$$

For the dataset depicted in Figures 6.3 and 6.5, $A = 1.5 \times 10^{-7}\,\mathrm{V\,m^{-1}}$. Knowledge of the conversion factor and κ makes the calibration procedure complete, and the forces exerted by the optical trap and the distances moved can easily be found.

6.4
Concerns

6.4.1
Biological Damage

Already, in the first trapping experiments using an argon ion laser with a wavelength of 514.5 nm, Ashkin had noticed a significant damage of the optically trapped latex particles (Ashkin *et al.*, 1986). The particles shrank in size until they finally disappeared. Possible damage on the trapped specimen induced by the laser light is a very appropriate concern to address.

The optical damage, the so-called opticution, depends on a number of factors, for example the wavelength of the trapping laser, the intensity of the laser light, and the presence of possible toxic radicals in the sample. In general, the longer the wavelength, the less is absorbed by biological specimen. In contrast, the longer the wavelength, the more pronounced the absorption of water, resulting in a heating of the sample. There seems to be a window of laser wavelengths around 800–1100 nm where the absorption by both biological specimen and water is so small that for many practical purposes it can be ignored. A wavelength of 1064 nm is very commonly used for optical trapping, because there exist YAG lasers with very high-quality Gaussian intensity profiles emitting at this wavelength.

The common notion that optical trapping essentially is not destructive, provided there is a correct choice of laser wavelength, first came about when A. Ashkin, in 1987, showed trapping of living microorganisms, which were even able to proliferate during the trapping (Ashkin, Dziedzic and Yamane, 1987). Since then, optical tweezers have been very extensively used to probe biological specimen at the nano level. Often, a handle in the form of, for example, a polystyrene bead is specifically attached to the system of interest. The optical trap then acts on the handle and hence, not on the biological system itself. The size of the trap is diffraction limited and hence does not exceed 1 μm^3. Therefore, it is fair to assume that the biological specimen is not significantly perturbed by the presence of the trap. However, the attachment of the handle might have an effect.

Recent experiments challenge the notion that optical trapping does not have a physiological effect, especially if the biological specimen is directly trapped. A study of how *Escherichia coli* bacteria were able to efficiently rotate their flagella while being optically trapped (Neuman *et al.*, 1999) showed that the tweezing indeed did have an effect. The higher the intensity of the trapping laser light, the lower was the rotational frequency. Also, they saw a pronounced effect with varying wavelengths, with 870 and 930 nm causing the most damage, and 830 and 970 nm, the least. They also proposed that the *E. coli* bacteria are increasingly sensitive in the presence of oxygen radicals, possibly produced by the trapping laser.

Other studies have shown that gene expression in *Caenorhabditis elegans* held in an optical trap could be induced more by a certain wavelength and less by other wavelengths. The stress response increased with laser power and irradiation time (Leitz *et al.*, 2002). Also, it has been shown that various bacterial types, for example *E. coli*, *Salmonella*, and *Bacilus subtilus*, are not capable of maintaining the physiologically necessary pH gradient across the outer cell wall while they are being optically trapped, this effect showing up even at very low laser intensities (Rasmussen *et al.*, 2008).

Hence, it seems a fact that living organisms do experience physiological stress upon optical trapping regardless of intensity and wavelength used. And, for each application, one has to judge whether this is considerable.

6.4.2
Heating of Specimen

Another issue concerning optical trapping is the possible heating of the specimen. The degree of heating is related to the amount of energy absorbed and the heat conductive properties of the surrounding solution. Peterman, Gittes and Schmitt (2003) have addressed this issue and found that under normal trapping conditions for example trapping a polystyrene particle in an aqueous solution with a 1064-nm laser and an intensity of 20 mW, the heating is significantly less than 1 °C. However, if trapping is performed, for example, in glycerol or other poorly conductive media, or if higher laser powers are used, one should be aware of a possible significant heating.

6.5
Technical Improvements

While operating in the nanoworld, it is always a challenge to minimize noise. Optical tweezer setups typically suffer from mechanical drift in various parts of the equipment. Therefore, efforts have been put into making very stable setups, which include minimizing air currents, mechanical drift of stages, and so on. One way of eliminating the effect of drift is to have two traps in the sample originating from the same laser beam and to use one of these traps to monitor the drift of a reference point, a fiducial mark; this drift can then be subtracted from the actual measurements thus significantly increasing the spatial resolution down to fractions of a nanometer (Nugent-Glandorf and Perkins, 2004).

Another very useful improvement is the so-called force clamp, which is a feed-back mechanism ensuring a constant force acting by the optical trap despite possible motion of the trapped specimen.

6.5.1
Multiple Optical Traps

In principle, the only necessary condition to trap a particle with an index of refraction different from the surroundings is to have an appropriate light intensity gradient. Hence, different trapping schemes with various intensity profiles can be imagined. One useful technique is the so-called multiple-beam optical tweezers, which are capable of trapping and manipulating up to hundreds of particles simultaneously in three dimensions. Multiple-beam optical tweezers can be constructed in fundamentally different ways. One of these is by means of a diffraction grating, a hologram, which is placed in the beam path typically before the telescope. When the beam hits the hologram it is split into a number of less intensive beams, each of which acts as an optical trap. This creates "holographic optical tweezers" (Curtis, Koss and Grier, 2002).

Other ways to construct multiple-beam optical tweezers include using a spatial light modulator (SLM) to impose a prescribed amount of phase shift at each pixel in an array by varying the local optical path length. Typically, this is done by controlling the orientation of molecules in a layer of liquid crystals. The generalized phase contrast technique is an elegant variation of this, which, by a simple computer interphase can be used to create arbitrary trapping schemes (Rodrigo, Daria and Gluckstad, 2004).

Such arrays of optical traps hold great promise, for example, for making 3D colloidal structures, for microassembly, sorting (MacDonald, Spalding and Dholakia, 2003), and manipulation. One drawback, however, is that, at present, no calibration methods are available for

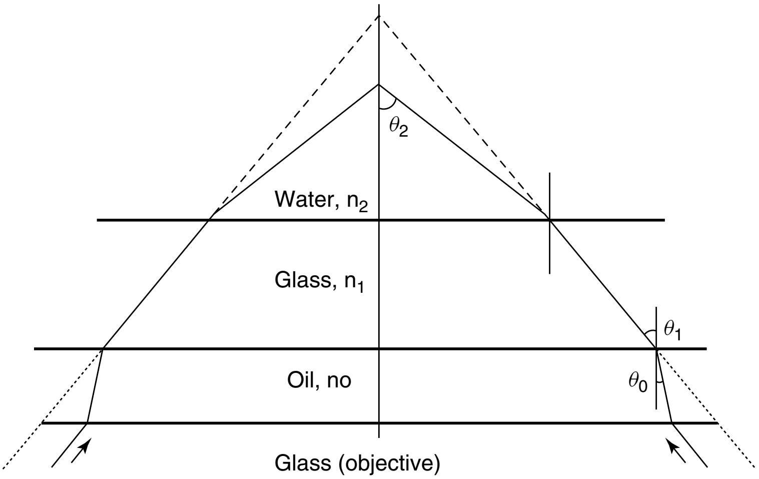

Fig. 6.8 Schematic drawing of marginal rays. At all interphases between media with different index of refraction, the rays are bend, hence giving rise to a defocusing of the optical trap.

multiple traps, hence, the forces cannot be either controlled or measured. Also, if many traps are made from the same laser beam, each of them is typically weak, sometimes only capable of two-dimensional trapping.

6.5.2
Compensating Spherical Aberrations

Because of possible opticution and heating of the sample, it is important to have as efficient an optical trap as possible, that is to use as little power as possible to create a trap of a given strength. When the laser beam passes from a media with one refractive index to a media with a different refractive index, for example, from the immersion media to the glass coverslip, and again from the glass coverslip to the sample environment, it undergoes refraction as sketched in Figure 6.8. The refractive angle depends on the distance to the center of the beam. Therefore, this refraction defocuses the laser light in the specimen, thus giving rise to a concept known as *spherical aberration*, which weakens the optical trap. Therefore, to have an efficient trap, it is desirable to avoid or minimize spherical aberrations.

Oil immersion objectives can have higher numerical aperture than water immersion objectives. Hence, in principle, they hold potential for producing stronger traps. However, because of the presence of immersion oil in the optical path, oil immersion objectives produce optical traps that suffer significantly more from spherical aberrations than traps produced by water immersion objectives. Hence, microscope manufacturers optimize the objectives to work with visible light so as to have as few distortions as possible for the corresponding wavelengths. However, most optical tweezers used to manipulate biological specimen are based on infrared lasers, which suffer significantly from spherical aberrations if focused by typical high numerical objectives.

One solution to the problem of induced spherical aberrations is to use another source to cancel the spherical aberrations induced along the beam path. An easy and very efficient method is simply to change immersion media to an oil with a higher refractive index (Reihani and Oddershede, 2007). This method increases the efficiency of a typical optical trap by a factor of 3. Another way of compensating spherical aberrations is by changing the length of the focusing tube (Reihani, Khalesifard and Golestanian, 2006). By combining these two methods, optical trapping of hundreds of microns can be performed very efficiently inside an aqueous sample, even by using an oil immersion objective.

6.6
What Can Be Trapped?

In the 1980s, Ashkin demonstrated single beam three-dimensional optical trapping of dielectric beads ranging in size from 26-nm silica beads to latex or polystyrene beads of several microns. Also, he demonstrated trapping of living bacteria, yeast, and virus. Optical trapping of metallic nanoparticles was first done by Svoboda and Block (1994), who trapped 36.2-nm gold nanoparticles. The forces acting on such small metallic particles are significantly larger than on, for example, latex particles of similar size. Hence, metallic nanoparticles hold great potential as handles for nanoscientific applications. Later, 3D optical trapping of individual gold nanoparticles with diameters ranging from 18 to 254 nm was achieved (Hansen, Bhatia and Oddershede, 2005), and even quantum dots could be optically manipulated.

Basically, all living cells can be individually trapped and manipulated, and even organelles inside living cells can be trapped (without perturbing the cell wall).

In principle, any object with dielectric properties that are different from the surroundings can be trapped with a proper detection scheme, provided that the trapping potential is deeper than the typical thermal energy of the particle. In Hansen, Bhatia and Oddershede (2005), the trapping potentials for gold nanoparticles have been calculated by integrating Eq. (4). For a metallic particle with diameter 20 nm the potential depth is $\sim 20\ k_BT$, whereas for a 12-nm particle it is $\sim 2\ k_BT$ (assuming a laser power of 800 mW). Hence, the limit of optical trapping of metallic nanoparticles probably is around 10–12 nm.

6.7
Applications

Optical tweezers are very versatile tools. This, along with the fact that they can be made nearly noninvasive, makes them perfect to study biological organisms and molecules at the micro and nano levels. One of the largest accomplishments mediated by optical tweezers is the unraveling of the functioning of individual biological molecules. Optical tweezers allow for the study of an individual molecule, thus with the potential of revealing spatial and temporal inhomogeneities that are masked in ensemble measurements. As a ‘‘macroscopic’’ example, let us imagine we are looking at a crowd of people from a distance. Let us suppose that half of the persons are blue, half are yellow, and that they are mixed together. From our point of view, the crowd appears green, but it would an erroneous conclusion to draw that the individuals are green. To really understand the nature of the crowd, the individuals need to be investigated.

6.7.1
Molecular Motors

A molecular motor is a single biological molecule that performs a biased motion and burns some fuel (typically in the form of triphosphates). Significant work has been performed using optical tweezers to pinpoint working mechanisms, such as typical speeds, stalling forces, and step sizes of molecular motors. In these experiments, a bead is typically and specifically attached to the molecule of interest, the bead being used as a handle for the optical techniques. In the following, a couple of the first molecular motors uncovered are described.

6.7.1.1 Kinesin

Kinesin is a two-headed molecule that moves along microtubules, thus mediating intracellular transport. It is a highly progressive molecule, typically taking hundreds of steps along the microtubules before falling off. (Schnitzer and Block, 1997) have done a careful investigation of this molecular motor. Using an attached silica bead as a handle for the optical trap, they studied the motion of the molecule. Without an optical trap present, the attached bead would perform a Brownian diffusion with an amplitude significantly larger than the step size of the motor. By holding the bead within the optical trap, the Brownian fluctuations are largely suppressed, hence, a step size of only 8 nm was resolved. Also, it was proved that a single ATP is hydrolyzed per step. Several mechanisms for kinesin movement can be envisioned; amongst the published suggestions are the hand-over-hand or the inch worm models. At present, the most favored model is a slightly asymmetric hand-over-hand mechanism (Asbury, Fehr and Block, 2003).

6.7.1.2 RNA Polymerase

RNA polymerase moves along DNA while performing transcription, that is copying the information stored in DNA into an RNA copy. The polymerase is also highly processive as it moves from the promotor site to the stop signal. By attaching the polymerase to a surface and attaching a bead, held by an optical trap to one end of a DNA string, the action of the RNA polymerase was investigated (Wang *et al.*, 1998). The polymerase was found to move with an average velocity of 16 nucleotides/s, corresponding to $\sim 5\,\mathrm{nm\,s^{-1}}$. By increasing the force applied with the optical trap on the motor the stalling force, causing the RNA polymerase to arrest, was found to be 30–35 pN.

6.7.1.3 Viral Rotary Motor

Viruses are tiny organisms, on the order of 50 nm in diameter, containing their heritage material very densely packed in a capsid. Upon infection, the virus squirts its heritage material through the cell wall of the host organism. The viral bacteriophage $\phi 29$ packages its 6.6-µm long DNA into its nanocapsid. This process is done by a rotary motor, the efficiency of which is remarkable because DNA must be packed to nearly crystalline density. The motor was studied by optical tweezers by Bustamante and coworkers (Smith *et al.*, 2001) where they investigated the action of the motor against an applied force. The motor is very strong, capable of working against a load of 57 pN, and it has an initial packaging rate of ~100 basepairs/s, corresponding to ~33 nm s^{-1} of DNA. Also, the motor is highly processive, working over lengths of 5 μm.

6.7.2
Unfolding/Disassembly of Macromolecules

Optical tweezers can exert forces up to some hundreds of pico-Newtons. They operate in a force regime lower than the atomic force microscope, which typically operates in the nano-Newton range. Macromolecules can be unfolded by any nanotool capable of applying forces in the correct regime, and whether tweezers or an atomic force microscope is preferable depends on the structure investigated. However, a problem common to any technique applied to unfold macromolecules is the fact that the force needed to unfold a given structure, and the time it takes before the structure unfolds, is highly dependent on the loading rate with which the force is applied. In principle, if one waits for a long enough time, any structure will unfold even in the absence of an external load. In the presence of an external load, the free energy as a function of the reaction coordinate is tilted (Wang *et al.*, 1998), and if the energy barrier is lowered, then the reaction will take place significantly faster. The interpretation of such nonequilibrium unfolding curves is not trivial, but can be done by the procedures proposed by Jarzynski (1997) or Crooks (1999).

6.7.2.1 Release of DNA from Nucleosomes

Nucleosomes organize eucaryotic DNA by wrapping it around the nucleosomes. The DNA on the nucleosomes is in a condensed state, also permitting regulated access to genetic information contained therein. Using optical tweezers, the dynamic structure of individual nucleosomal arrays was investigated by Wang and coworkers (Bower-Toland *et al.*, 2002). They find a reversible, multistage release of DNA with 76 basepairs being released at relatively low stretching force, at higher force 80 basepairs were released, and finally the histones were completely detached. These experimental observations form the basis of a ‘‘three-stage’’ model of nucleosomal opening.

6.7.2.2 RNA Structures

Optical tweezers have also been used to unfold secondary and tertiary mRNA structures. One example is the unfolding of RNA hairpins (Liphardt *et al.*, 2001). The RNA hairpin setup was also used as an example of how to apply the methods suggested by Jarzynski (1997) and Crooks (1999) for a correct treatment of an unfolding process through a nonequilibrium pathway.

mRNA pseudoknots are tertiary structures, which are often used by viral pathogens to induce frameshifting. Frameshifting is a mechanism by which the translating ribosome slips backward by one nucleotide and hence experiences a reading frame different from the original one. Optical tweezers were used to mechanically unfold structurally nearly identical mRNA pseudoknots, but which give rise to significantly different degrees of frameshifting (Hansen *et al.*, 2007). The conclusion was that the degree of frameshifting was correlated to the mechanical strength of the pseudoknot, thus indicating a physical mechanism for frameshifting.

6.7.3
Cell Biophysics

As optical tweezers are the only nanotool presently available that is capable of manipulating and measuring forces inside living cells in a nearly noninvasive fashion, they hold great potential use in cell biophysics. For instance, optical tweezers have found use in probing microrheological environments both of *in vitro* actin-based networks (Mizuno *et al.*, 2007) and inside living organisms (Tolic-Nørrelykke *et al.*, 2004). In comparison with the *in vitro* single-molecule experiments, probing a living organism has the advantage that the physiological conditions are biologically correct and relevant. However, interpretation of the results can be difficult because of the presence of a number of uncontrollable factors.

6.8
Future Directions

In the future, the limits of optical trapping will be pushed toward finer resolution and faster detection. Probably, efforts will be undertaken also to produce stronger traps, and to implement traps, for example, into lab-on-a-chip systems.

Combinations of optical tweezers with other techniques such as fluorescence, or even single-molecule fluorescence are beginning to appear (Lang *et al.*, 2004). Such combinations hold huge potential, for example, using the optical tweezers to apply a force to a particular structure, say, a molecule and to observe how the intrinsic components of the structure react to the applied force. Such experiments could shed light on the question of the sequence in which a protein folds and unfolds, or, for instance, how the use of energy is coupled to mechanical action of a molecular motor.

7.1 Introduction

If proteins were in a unique conformation, without a hydration shell and a bulk solvent, they could not function. Proteins, however, are not in a unique conformation. They can assume a very large number of different conformational substates (CSs). At ambient temperature, they fluctuate continuously among the CSs. Working proteins consist of the folded amino acid chain, surrounded by a hydration shell, and embedded in a bulk solvent. All are involved in protein dynamics. The different CSs are organized in an energy landscape. A fundamental understanding of proteins and their functions must involve knowledge of the energy landscape, transitions among the CSs, and the influence of the hydration shell and the bulk solvent on the dynamics and the functions.

7.2 Supercooled Liquids and Glasses

Why discuss supercooled liquids and glasses? As will be shown below, the prominent motions inside proteins are slaved to the hydration shell and the bulk solvent. The hydration shell and the bulk solvent, however, are supercooled liquids or glasses, depending on the temperature. Information about their properties can therefore be extracted from the vast literature on such systems (Donth, 2001; Zalle, 1983; Brawer, 1985; Ediger, Angell and Nagel, 1996; Lubchenko and Wolynes, 2006). If a liquid is cooled, it can solidify discontinuously to a crystal. Some liquids resist forming a crystal even well below their freezing temperature; they become supercooled. Despite the technical importance of glasses and the challenging physics problems that they pose, standard condensed matter texts devote only few pages to them. The biological physicist has to resort to the few available books, reviews, and original papers to get the insight into the properties of amorphous systems that help understanding protein dynamics.

7.2.1 Glass Structure

A fundamental difference between a glass and a crystal is in the atomic-scale structure. Crystals are periodic and possess long-range order. Glasses are aperiodic and have no long-range order. In a crystal, every atom knows

ISBN: 978-3-527-40702-6

where its place is. Glasses are frustrated (Toulouse, 1977; Fischer and Hertz, 1991; Lubchenko, 2008); atoms compete for the same position and a given atom may have two or more quasi-equilibrium positions. Crystals are in equilibrium at all temperatures; glasses are metastable.

7.2.2
The Energy Landscape

Supercooled liquids and glasses can be described by an energy landscape (EL) (Goldstein, 1969) that is organized in a number of tiers. The top tier contains glasses with different overall structures, called *polymorphs* (Poole *et al.*, 1997). Each polymorph can exist in a vast number of structures that are locally different. The organization continues to substates with smaller barriers. There are, however, substantial differences between the glass and the protein landscapes: glasses have some deep and very narrow wells, representing crystals. Proteins cannot form crystals. What is called a protein crystal is a crystal in which the individual components are proteins. Each individual protein can assume a large number of different structures.

7.2.3
Viscosity, the Glass Transition, and Fragility

The viscosity, $\eta(T)$, of a supercooled liquid increases very rapidly with decreasing temperature. The glass transition temperature, T_g, is often defined as the temperature where $\eta(T_g) = 10^{13}$ P. (Viscosity is measured in poise (P) or pascal second (Pa s), where 1 P = 0.1 Pa s.) The temperature dependence of the viscosity can be approximated by the Vogel–Fulcher–Tammann (VFT) expression:

$$\eta(T) = \eta_0 \exp\{DT_0/(T - T_0)\} \qquad (1)$$

Here, D is called the *fragility*. T_0 is the temperature where the viscosity would diverge if Eq. (1) is still valid at T_0.

7.2.4
Fluctuation and Relaxation Processes

Supercooled liquids and glasses undergo thermal fluctuations at all temperatures. If pushed out of thermal equilibrium, for instance by a temperature or pressure jump, they relax to the new equilibrium. Fluctuations and relaxations are connected by the celebrated fluctuation–dissipation theorem (Kubo, 1966; Chandler, 1987). The literature covering these processes in glasses and supercooled liquids is immense, but a number of reviews and papers summarize the essential results (Toulouse, 1977; Richert and Blumen, 1994; Lunkenheimer *et al.*, 2000; Angell *et al.*, 2000; Richert, 2002; Affouard, Descamps and Ngai, 2006). Two main approaches are used to study relaxations, time-domain and frequency-domain techniques. In the time-domain technique, a rapid perturbation forces the system out of equilibrium to a new state. The relaxation to the new state is observed, for instance, optically by following the position of a spectral line. In simple systems, the relaxation usually has the form

$$\phi(t) = \phi(0)e^{-kt} \qquad (2)$$

where $\phi(t)$ describes a quantity characterizing the measurement, and k is the relaxation rate coefficient. In most complex systems, however, Eq. (2) is not adequate, but a stretched exponential,

$$\phi(t) = \phi(0)\exp\{-(kt)^{\beta}\} \quad (3)$$

with $\beta < 1$, often approximates the observed $\phi(t)$ in some systems. Sometimes a powerlaw,

$$\phi(t) = \phi(0)\{1 + \mathrm{const}(kt)^{\beta}\}^{-1} \quad (4)$$

provides a better fit. A remark on data evaluation is in order here. The standard approach of the past, still in vogue in many laboratories, is to fit $\phi(t)$ with two exponentials if one does not fit. This technique is related to the fact that kinetic data in these laboratories are traditionally plotted as $\phi(t)$ versus t. In the same laboratories data would never be plotted versus H, where H is the hydrogen ion concentration. Instead pH is used, where p denotes $-\log$. Similarly kinetic data should *always* be plotted versus $-\mathrm{p}\,t$, or $\log t$. Of course, if data are only obtained over a small time range, the form of plotting is irrelevant, but such data are not of much use. A figure of $\log\phi(t)$ versus $\log t$ helps to distinguish between two or more exponential processes and a single nonexponential process. Time-domain techniques permit measurements from below picosecond to longer than kilosecond.

The frequency-domain approach, promoted by Debye (1929), permits the study of relaxation processes over more than 18 orders of magnitude in frequency (Kremer and Schoenhals, 2003; Kaatze and Feldman, 2006), from about 10^{-6} to more than $10^{12}\ \mathrm{s}^{-1}$. In the broadband dielectric spectrometry, the sample is placed in a capacitor and exposed to a monochromatic electric field $\mathbf{E}(\omega) = \mathbf{E}_0\exp(-\mathrm{i}\,\omega t)$. The resultant polarization $\mathbf{P}(\omega)$ is measured as a function of the radial frequency ω that is connected to the "technical" frequency υ by $\omega = 2\pi\upsilon$. The radial frequency ω used in the frequency domain is identical to the rate coefficient k in the time domain. The sample properties are expressed in terms of the complex electric permittivity:

$$\begin{aligned}\varepsilon(\omega) &= \varepsilon'(\omega) - \mathrm{i}\varepsilon''(\omega)\\ &= 1 + P(\omega)/\varepsilon_0 E(\omega) \quad (5)\end{aligned}$$

Here, ε_0 is the vacuum dielectric permittivity. The real part $\varepsilon'(\omega)$ represents the component of $\mathbf{P}(\omega)$ that is in phase with $\mathbf{E}(\omega)$ while $\varepsilon''(\omega)$ has a $\pi/2$ phase shift. The frequency dependence of the complex permittivity is caused by the fact that the polarization of a material does not respond instantaneously to the applied electric field. The dielectric permittivity spectrum shows a number of dispersion phenomena. The fluctuation–dissipation theorem then implies that the same phenomena should also occur in the equilibrium fluctuations. This fact is important for protein dynamics.

7.2.5
Primary (α) and Secondary (β) Relaxations

A very large number of experiments in many different supercooled liquids and glasses demonstrate that two main classes of relaxation (fluctuations) processes occur, called α and β. A typical example (Deegan and Nagel, 1995) is shown in Figure 7.1a. The two processes are characterized by the temperature dependence of their rate coefficients $k_{\alpha}(T)$ and $k_{\beta}(T)$, obtained from the peak positions of the respective peaks in $\varepsilon''(\omega)$ (Ngai and Paluch, 2004). The α relaxation generally follows a VFT law, Eq. (1).

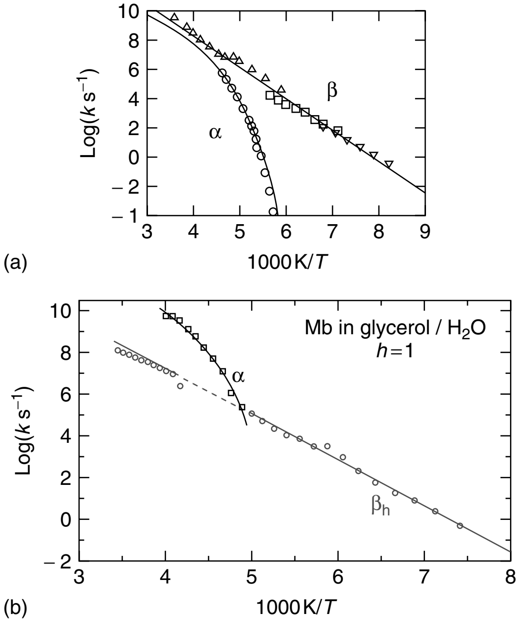

Fig. 7.1 (a) The temperature dependence of the α and β relaxations in a glass former (polybutadiene). (After Deegan and Nagel (1995).) The α relaxation can be approximated by the VFT relation, Eq. (1). The β relaxation follows the Arrhenius law. (b) The temperature dependence of the α and β_h relaxations in myoglobin embedded in a equal weight glycerol/water solvent, with hydration $h = 1$, where h is the weight ratio of water/protein.

The rate coefficient $k_\alpha(T)$ and the viscosity $\eta(T)$ are related by the mechanical Maxwell relation

$$k_\alpha(T) = G/\eta(T) \tag{6}$$

Here, G is a shear modulus that depends only weakly on temperature and on the material. At 300 K in glycerol–water mixtures G is approximately 4×10^{11} cP s^{-1}. The β relaxation usually follows an Arrhenius relation, $k_\beta(T) = A\exp\{H_\beta/k_BT\}$, and depends only weakly on viscosity. In some systems, more than one β relaxation occurs. Proteins surrounded by the hydration shell and embedded in a bulk solvent also show the α and β fluctuations (Figure 7.1b). The β relaxations in Figure 7.1a and b differ. In Figure 7.1a, the β relaxation is faster and appears to merge with the α relaxation at high temperature. In Figure 7.1b, the β relaxation crosses α and it continues to higher temperature, and is much slower than α above the crossing. It turns out that it originates in the hydration shell of the protein and we therefore denote it with a subscript "h".

7.3
The Energy Landscape of Proteins

Proteins, like glasses, can assume a large number of different CSs, distinguished by their different structures and dynamics. Evidence for the existence of CS in proteins comes from a wide variety of experiments, for instance nonexponential ligand binding (Austin *et al.*, 1975), the Debye–Waller factor in X-ray diffraction (Frauenfelder, Petsko and Tsernoglou, 1979; Garcia, Krumhansl and Frauenfelder, 1997; Chong *et al.*, 2001), and the width of spectral bands observed in various spectroscopies. If the number of different CSs were small, they could be individually described. The number is, however, extremely large and they can be characterized by introducing the EL, a construct in a high-dimensional space. At any instant of time, the structure of a protein, including its hydration shell and part of the solvent, is given by the coordinates $\mathbf{x_i} \equiv \{x_i, y_i, z_i\}$ of all N atoms in the protein, the hydration shell, and the adjacent solvent. The high-dimensional vector $\mathbf{x(t)} \equiv \{x_1, x_2, \ldots, x_N\}$ describes the structure at time *t*. To represent **x(t)**, the EL is introduced. It has about $3N$ coordinates, where N is about a thousand. The vector **x(t)** is a point in this space. These points, together with the barriers between them, form the EL. Changes of the protein structure in real space appear as the motion of **x(t)** in the hyperspace. Any attempt to draw the EL on a piece of paper always causes a headache. Nevertheless, such a figure can give some insight. Figure 7.2 is a projection of the EL on a "conformation plane". Each point in this figure describes one particular CS, given by the vector **x(t)**. The number of such points is extremely large, of the order of 10^{100}. Only a very small selection is shown. What has been gained by the introduction of the EL? Not much would be changed if the EL were featureless. However, in myoglobin (Mb) and most likely in all biomolecules the EL has energy valleys within energy values within energy valleys that are organized into a number of tiers. The top three tiers are relevant for function. Lower tiers do exist, which have been discovered in cryogenic experiments (Leeson *et al.*, 1997), but we do not know if they have functional importance. The top tier, tier 0, describes taxonomic substates; they are so called because they can be individually described and behave in some sense as if they are different proteins. They are the analog to polymorphs in glasses. In Mb, three taxonomic substates have been identified and two, called A_0 and A_1, have been explored in some detail. They have different functions (Frauenfelder *et al.*, 2001), catalysis and dioxygen storage, and can be described by their different spectra (Alben, 1982; Ansari, 1987) and different structures (Yang and Phillips,

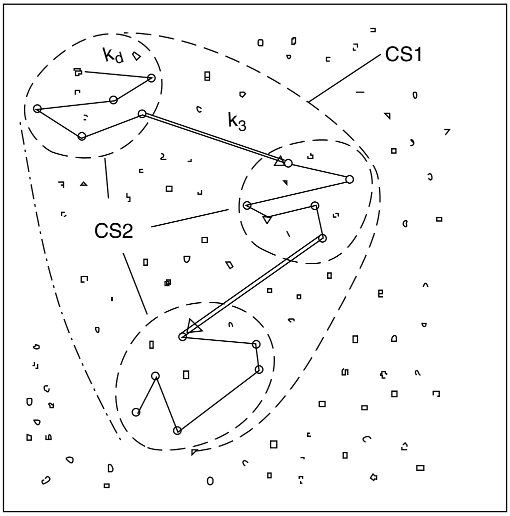

Fig. 7.2 The energy landscape. Each point represents a vector **x**(t) that describes the entire structure of the protein in a particular substate. Since 10^{100} of the order of CSs are there, only an extremely small selection is shown. A protein starting in a particular CS traces out a path in the EL that defines the substates in tiers 2 and 1.

1996). We now use the conformation plane to discuss tiers 1 and 2, and define these tiers by the average fluctuation rate coefficients at ambient temperature. Typical values are $k_\alpha \sim 10^{11}\ \mathrm{s}^{-1}$ and $k_\beta \sim 10^{8}\ \mathrm{s}^{-1}$ (Figure 7.1b). We therefore assign the α fluctuations to tier 2 and the β fluctuations to tier 1. Consider the fate of a protein starting out in a particular substate of tier 2. The protein will make a random walk, each step given by k_α. After an average of 10^3 steps, the protein uses a β fluctuation to jump to another substate of tier 1 where it will again remain approximately for the time $1/k_\beta$. These random walks trace out the CS2. A protein starting out in a different CS will also trace out CS2 and CS1. The EL is actually more complex than that that is shown in Figure 7.2. More work will be needed! (Frauenfelder, Sligar and Wolynes, 1991)

As discussed in Sections 7.6 and 7.7, both the α and β fluctuations are essential for motions in proteins. These fluctuations are actually not generated by the protein itself. The α fluctuations originate in the bulk solvent and drive these fluctuations in the protein. The β fluctuations originate in the hydration shell and generate internal protein motions. The beauty of work with proteins is that the two types can be separated. In a rigid solvent, the α fluctuations are so slow that they can be neglected. If the hydration shell is absent, there are no β fluctuations.

7.4
Vibrations and Normal Modes

In 1907, Einstein resolved a major difficulty in understanding the low-temperature behavior of the specific heat of crystals by quantizing the system, assuming that all atoms vibrate with the same frequency. Debye improved the model by considering the crystal as an elastic continuum. For proteins, these models are much too simple. Each protein atom can vibrate with its own frequency. What is of interest for dynamics are not these individual frequencies, but the normal modes (Cui and Bahar, 2006). These are time-independent constants of the motion and are described by the vibrational density-of-state spectrum, the number of normal modes per frequency interval (Hinsen, 2000; Melchers *et al.*, 1996). The normal modes are the solutions of the relevant eigenvalue equation. Modern computers can solve this equation even for proteins. Experimentally, information about the normal mode spectrum has been obtained, for instance, by using the phonon-assisted Mössbauer effect (Achterhold *et al.*, 2002) or by high-resolution X-ray measurements (Leu *et al.*, 2005). Normal mode analysis has limitations. Barriers between substates can be so high that vibrations cannot overcome them. Molecular dynamics calculations complement the normal mode approach by also investigating jumps between wells (Garcia, 1992; Kitao, Hayward and Go, 1998; Becker *et al.*, 2001).

7.5
Proteinquakes

An earthquake is the result of a sudden release of stored energy in the Earth's crust. Tectonic earthquakes caused by a sudden slip of plates result in two observables, the changes in "conformation" along the fault and seismic waves. Quakes occur on the moon, the planets, the sun, stars, and in proteins (Ansari *et al.*, 1985). Consider myoglobin in the bound-state structure. A laser flash breaks the CO–Fe bond and the protein relaxes to the deoxy structure. Part of the released energy is emitted as waves. When compared to the total binding energy of the system, proteinquakes are more powerful than earthquakes or starquakes, because the released bond energy can be of the same order of magnitude as the binding energy of the protein, about 100 kJ mol^{-1}. Proteinquakes show the two characteristic features of quakes, changes in the conformation and the emission of waves. Evidence for a structural change during a proteinquake comes from the fact that the X-ray structures of the MbCO and deoxyMb are different. Synchrotron radiation gives far more information; it permits the study of the time-dependence of the structure during the quake (Teng, Srajer and Moffat, 1994; Bourgeois *et al.*, 2006). Very fast volume changes, which are the equivalent of the waves in earthquakes, have also been observed (Miller, 1994; Nagy, Raicu and Miller, 2005). The primary features of proteinquakes are thus established. The properties of the structural changes in the quakes in Mb and also in other proteins, for instance in the photoactive yellow protein (PYP) (Xie *et al.*, 2001; Ito and Sasai, 2004), remain to be explored. The fluctuation–dissipation theorem implies that the motions seen in proteinquakes also appear in thermal fluctuations. Indeed, entrance of a ligand such as dioxygen into a protein and diffusion through the protein involve fluctuations. Experiments and computational and theoretical treatments (Onuchic and Wolynes, 1993; Dellerue *et al.*, 2001; Miyashita, Onuchic and Wolynes, 2003; Miyashita, Wolynes and Onuchic, 2005; Okazaki *et al.*, 2006) show the crucial roles of proteinquakes and the related fluctuations in protein function.

7.6
The α Fluctuations and α Slaving

The complexity of the EL implies that proteins can undergo a range of fluctuations and relaxations. Rather than studying the individual motions in many proteins as is often done in computational approaches, deeper insight comes from looking at general features. Experiments over a broad range of temperature and using Mb embedded in cryosolvents provide such information. The effect of solvent viscosity on the dynamics of myoglobin is crucial (Beece *et al.*, 1980; Doster, 1983; Sage, Shoemaker and Champion, 1995; Kleinert *et al.*, 1998; Shibata, Kurita and Kushida, 1999; Fenimore *et al.*, 2002). A problem arises in the interpretation of such experiments. Although the viscosity in the bulk solvent can be measured, the viscosity in the interior of a protein must be calculated (Ansari, 1999). It is therefore better to use the dielectric relaxation rate coefficient $k_\alpha(T)$, which is related to the viscosity by the Maxwell relation (Eq. (5)). The experiments show that large-scale motions depend strongly on viscosity (Shibata, Kurita and Kushida, 1999). Examples of such large-scale motions are the exit of ligands from myoglobin, the exchange between taxonomic substates, and fluctuations of the entire protein. The protein motions follow $k_\alpha(T)$ over many orders of magnitude in rate, but are slower by large factors. This observation leads to the concept of slaving: large-scale protein motions follow the large-scale α fluctuations in the bulk solvent, but can be slower. Large-scale protein motions are not like opening and closing a rigid gate; they take place in a large number of small steps. These motions can be understood in terms of the hierarchical EL. Assume that the initial state i represents a closed conformation, with CO inside the protein, and f the substate where a gate to the solvent is open. Assume further that each step occurs with a rate coefficient $k_\alpha(T)$ and that the protein makes $n(T)$ steps to reach the open conformation. The exit rate is then given by

$$k_{\text{exit}}(T) = k_\alpha(T)/n(T) \tag{7}$$

The fluctuations in the protein follow the fluctuations in the solvent over about eight orders of magnitude, justifying the concept of slaving: The protein follows the solvent and not the other way around (Fenimore *et al.*, 2005). Moreover, the protein follows the solvent up to the smallest solvent viscosity, about 1 cP. It is therefore the protein that adjusts to the solvent. The protein behaves more like a liquid than a solid (Doster, Cusack and Petry, 1990; Hinsen *et al.*, 2002). The internal protein viscosity is about 1 cP, or even smaller, in agreement with Ansari's calculation, which shows that the internal friction is similar to that of water (Ansari, 1999). The bulk solvent contributes the enthalpic barrier and the protein contributes the entropic barrier for the control of large-scale protein motions. Slaving is also important for protein folding (Frauenfelder *et al.*, 2006). Lubchenko and Wolynes have formulated a theory of slaving (Lubchenko, Wolynes and Frauenfelder, 2005; Lubchenko, 2006). The theory shows how the molecular motions of the glass-forming solvent distort the boundary of the protein, thereby slaving large-scale conformational motions of the protein.

7.7
Internal Motions, Hydration, and β Slaving

Most protein functions stop below 200 K and it is often claimed that below this temperature proteins undergo only harmonic motions. However, internal motions, for instance the transit of small molecules from one cavity to another or some enzymatic reactions, occur well below 200 K. The α fluctuations alone cannot be responsible for these internal motions because internal motions occur even in a solid bulk environment, which suggests different fluctuations must be responsible. Therefore, the β fluctuations, briefly introduced in Section 7.2, are candidates for these internal motions. Experiments support this suggestion: (i) the internal motions continue even if the protein is encapsulated in a solid environment, such as poly(vinyl) alcohol (Austin *et al.*, 1975); (ii) internal motions disappear if the protein is dehydrated; and (iii) the activation enthalpies of the internal ligand transit are of the order of 40 kJ mol^{-1} (Sage, Shoemaker and Champion, 1995). The activation enthalpies of the β fluctuations in thin water films on a wide range of substances cluster around 45 kJ mol^{-1} (Swenson, Jansson and Bergman, 2006). These three observations together suggest that the hydration shell (Rupley and Careri, 1991; Halle, 2004; Levy and Onuchic, 2006; Helms, 2007), about two layers of water surrounding the protein, is the source of the β fluctuations. Experiments to test this conjecture lead to a remarkable conclusion: The internal motions as seen by the heme iron in myoglobin and the internal hydrogen protons, mainly in the side chains of the backbone, follow the β fluctuations in the hydration shell. The fluctuations in the hydration shell are measured using dielectric spectroscopy, and the internal motions are observed using the Mössbauer effect (Goldanski and Herber, 1968; Parak, Knapp and Kucheida, 1982) and neutron scattering (Doster, Cusack and Petry, 1989). Comparison of the external fluctuation rates to the internal fluctuation rates shows that the fluctuations seen by the heme iron and the hydrogen atoms follow fluctuations in the hydration shell. The conclusion is surprising. Naively one would expect that different parts of the protein's interior fluctuate with different rates. The observation that the heme iron and interior protons fluctuate similar to the hydration shell suggests a different picture: major internal motions are governed by the β fluctuations in the hydration shell. In other words, internal motions are slaved to the motions in the hydration shell. A word of caution. The results discussed here are relatively new and they have mainly been obtained by using one protein, myoglobin. The experiments have to be repeated, extended, and applied to other proteins and also to nucleic acids. Moreover, the fact that major motions can be explained as being due to the α and β fluctuations does not mean that other fluctuations do not play a role (Fenimore *et al.*, 2004).

7.8
Experimental

Conformational fluctuations in biomolecules extend from below picosecond to above kilosecond, more than 15 orders of magnitude. They involve small-scale and large-scale motions and can depend on external factors such as temperature, pressure, hydration, pH, viscosity, and solvent composition. It is obvious that no single technique and no single experiment can provide all the information necessary to fully understand biomolecular dynamics. The fact evident from experiments is that data taken over a small range of variables, such as measurements at one temperature only, one viscosity only, a small range of time say 1–100 ps, or one hydration level, cannot give the insight into the dynamics that is needed to understand the connection between motions and functions of protein. Nearly every modern experimental technique provides part of the necessary information. Many of the important approaches are discussed in other chapters of this volume or in the various Annual Reviews. Connecting experimental studies to computational and theoretical work is also needed to reach a picture with predictive power. Here, we provide a potpourri of a few useful experimental techniques and give relevant references.

Two properties of proteins determine what types of experimental techniques are most useful. The first property is the inherent existence of CSs. Proteins are highly inhomogeneous and not two in a sample have exactly the same structure and the same dynamics; protein properties must be described by distributions. In many instances, such distributions can be extracted from bulk experiments. Single-molecule experiments, however, give direct information. The second property is the observation that protein motions are to a large extent slaved to the fluctuations in the hydration shell and the bulk solvent. Thus, motions in the interior, the hydration shell, and the bulk solvent should be measured separately.

7.8.1
Single-Molecule Experiments

Because a protein can assume an extremely large number of conformations, any experiment on a sample yields an average result. Single-molecule experiments provide complementary information to bulk data (Deniz, Mukhopadhyay and Lemke, 2008).

7.8.2
Slaving Experiments

The relaxation and fluctuation experiments have already been described in Section 7.3. Broadband dielectric spectrometry is an excellent tool to study the α and β fluctuations in the bulk solvent and the hydration shell over a very wide range of time and temperature. As already pointed out, the two can be separated. In a solid bulk, the α fluctuation is essentially absent. The β fluctuation is absent in a dehydrated protein. The internal fluctuations can be observed with many different techniques. The Mössbauer effect and neutron scattering (Bée, 2003) have already been mentioned. Other techniques such as nuclear magnetic resonance (NMR) (Palmer, 2001; Mittermaier and Kay, 2006; Henzler-Wildman and Kern, 2007) also can yield the insight. But note that measuring only at one temperature does not provide the critical information whether two fluctuation processes with different rates are related or are independent (Lu, Xun and Xie, 1998; Michalet, Weiss and Jäger, 2006; Myong, Stevens and Ha, 2006; Joo *et al.*, 2008).

8.1
Introduction

Experiments have provided a wealth of structural and functional data for protein systems, yet atomic-level descriptions and femtosecond time resolution remain out of the reach of experimental techniques (Karplus and Petsko, 1990). With improved computational resources available today, molecular dynamics (MD) simulation has become an essential tool for investigating a wide range of biological phenomena. Recent advances in structural determination of proteins with electron microscopy, nuclear magnetic resonance (NMR), and X-ray diffraction have provided a springboard from which computer simulation can be used to obtain a deeper understanding of function. The aim of this chapter is to overview present-day MD methods, molecular mechanical (MM) force fields, and quantitative analysis, and to explore the challenges facing studies of protein structure and function today.

The first MD simulations of condensed-phase systems used highly simplified potential functions for simple systems such as hard-sphere models of liquid argon or the simple three-point water model (Alder and Wainwright, 1957; Rahman, 1964; Rahman and Stillinger, 1971). Atomistic computer simulations of proteins date back to 1977, when McCammon and Karplus reported a 10 ps simulation of the bovine pancreatic trypsin inhibitor (BPTI), containing 58 amino acids or $\sim$ 600 atoms (McCammon *et al.*, 1977). The first simulations of myoglobin in 1979 (Case and Karplus, 1979) revealed a path for O_2 access to the heme pocket that was not evident in crystal structures (Perutz and Mathews, 1966; Takano, 1977), demonstrating the utility of dynamic simulations of proteins. However, it is only in the last decade that enough computer power has been available to allow simulation of large protein–solvent systems with accurate parameterizations and today a great diversity of systems have been studied. Protein sizes range from hundreds of atoms, e.g. gramicidin (Allen *et al.*, 2003b) to large protein clusters, viral capsids or cell organelles comprising millions of atoms with simulation times spanning up to microseconds (Arkhipov *et al.*, 2006a; Arkhipov *et al.*, 2006b; Gumbart and Schulten, 2006; Freddolino *et al.*, 2006; Kitao *et al.*, 2006; Sanbonmatsu and Tung, 2007; Freddolino *et al.*, 2008; Jayachandran *et al.*, 2006). We are now at an exciting point in time for computer

simulation of proteins, but one where we must ensure accurate descriptions of protein interactions and develop rigorous statistical mechanical methods for computational analysis.

MD simulations can be performed using different levels of theory depending on the size of the system and the timescales of the protein motions of interest. In addition, the protein environment can be the dominant factor in determining system size, with water usually constituting the majority of the simulation system. Furthermore, the timescales of protein fluctuations can range from multi-femtosecond bond vibrations to millisecond to second global protein motions and folding. The challenge, therefore, is to use the best level of theory possible to describe the system that is tractable, given its size and timescales of interest. Arguably, the highest level of theory available for protein simulation is quantum mechanics (QM), which includes *ab initio*, density functional theory (DFT) and semiempirical methods, all of which explicitly describe electronic structure. DFT-based MD simulations, based on the Car–Parrinello formalism (Car and Parrinello, 1985), are emerging for protein modeling (Andreoni *et al.*, 2001), but are limited to hundreds of atoms and tens of picoseconds; well below the timescales of protein function. Recently, some advances have been made in the development of linear-scaling semiempirical methods, which allow for systems of thousands of atoms (Yang and Lee, 1995; Lee *et al.*, 1996; Dixon and Merz, 1997; Anikin *et al.*, 2004). However, hybrid QM/MM methods, pioneered by Warshel and Karplus (1972), have evolved as a valuable tool for studying protein structure and dynamics (Gao *et al.*, 2008). In this approach, the system is divided into a small QM region and a large MM region that encompasses all other atoms. (Warshel and Levitt, 1976; Bash *et al.*, 1987) The challenge remains to optimally separate QM and MM regions and to extend to greater system sizes and timescales (Gao *et al.*, 2008).

At the other end of the spectrum, coarse-grained (CG) methods (Levitt and Warshel, 1975), where each amino acid residue is represented by one or a few particles, have been developed to permit extension to greater sizes and timescales (Nielsen *et al.*, 2004; Tozzini, 2005; Biggin and Bond, 2008; Monticelli *et al.*, 2008) These methods can be used for multi-microsecond to millisecond simulations for millions of atoms (Nielsen *et al.*, 2004). Therefore, they can, in principle, be used to study protein folding (Tozzini, 2005), membrane protein insertion into lipid bilayers (Biggin and Bond, 2008) and simulation of large molecular complexes such as the ribosome (Trylska *et al.*, 2005) and nucleosome (Voltz *et al.*, 2008). Multiscale approaches, which combine atomistic MM and CG methodologies for large biomolecular systems, can allow for extended system sizes while maintaining atomic level information for protein function, which is currently an active area of development (Ayton *et al.*, 2007; Ayton *et al.*, 2008; Praprotnik *et al.*, 2008).

However, fully atomistic MD simulation with classical force fields form the heart of present-day protein simulation because of their realistic descriptions of protein–protein, protein–ligand, and protein–nucleic acid interactions and their ability to cover much of the relevant length and timescales for protein function. MD simulation can complement experimental observations by not only depicting molecular motions and interactions, but also by providing quantitative measures of function (Becker *et al.*, 2001; Kukol, 2008; Karplus and McCammon, 2002). Here we describe some of the challenges facing quantitative descriptions of protein function with MD simulation due to timescales and MM force field descriptions. We illustrate the successes and challenges by investigating particularly challenging applications involving simple model membrane-protein systems. Membrane proteins make up one-third of the human genome and over 70% of drug targets. They carry out vital physiological functions in the body. While there has been much experimental progress in understanding the structure and function of these proteins, a molecular-detail description has not been fully resolved. In this chapter we concentrate on exploring computational methodologies to understand the microscopic mechanisms of membrane protein function. We particularly focus on ion channel proteins that facilitate the selective transport of charged molecules across cell membranes and which are associated with many neurological and cardiovascular disorders (Ashcroft, 2000).

Ion translocation is an electrodiffusive process, in which specific channels can distinguish between different ions on the basis of valence and size (Hille, 2001). After the pioneering studies of Hodgkin and Katz (1949), Hodgkin and Huxley (1952), nearly 60 years ago, many structural and functional studies have sought to understand the mechanisms of permeation and selectivity. Recent successes in structural determination of ion channel proteins (Doyle *et al.*, 1998; Jiang *et al.*, 2002; Jiang *et al.*, 2003a; Miyazawa *et al.*, 2003; Chang *et al.*, 1998; Dutzler *et al.*, 2002) have provided a solid basis for detailed mechanistic studies. Ion channels also profit from decades of studies examining sensitivity to physiological and pharmacological conditions (Seeman, 1997; Hille, 2001). Yet, to fully understand the mechanisms of ion permeation and selectivity, one needs to understand the atomic breakdown of ion channel energetics. We also report studies that explore the ability of charged proteins to move within membranes to understand the voltage gating of potassium channels. Both of these studies push the limits of classical force fields, beyond what was originally envisaged when the force fields were developed, and require extensive thermodynamic analysis to extract the mechanisms of protein function.

8.2
Molecular Mechanical Force Fields

An empirical force field is a combination of a potential energy function, $U(\mathbf{R})$, describing the molecular system as a function of coordinates of the constituent atoms, $\mathbf{R}$, along with a set of empirically derived parameters. Simple empirical energy functions for computer simulation have been used for more than three decades for simple organic molecules (Burkert and Allinger, 1982) and biological systems (McCammon *et al.*, 1977). Examples of empirical force fields commonly used for protein simulations include Amber (Cornell *et al.*, 1995), CHARMM (MacKerell, 1998b), GROMOS (Oostenbrink *et al.*, 2004), and OPLS-AA (Jorgensen *et al.*, 1996), as well as other more general force fields for organic and biological molecules (Rappe *et al.*, 1992; Allinger *et al.*, 1996; Halgren, 1996; Oldziej, 2005; Daggett, 2006). There is also a broad category of CG force fields, in which a group of atoms or molecules is treated as single particles (Nielsen *et al.*, 2004). Here the main focus is on the atomistic force fields for which, arguably, the most realistic models of protein systems exist today. The popular software packages, which can be used for protein MD simulations include AMBER (www.ambermd.org) (Weiner and Kollman, 1981; Pearlman *et al.*, 1995; Case *et al.*, 2005), CHARMM (www.charmm.org) (Brooks *et al.*, 1983; MacKerell *et al.*, 1998a), GROMOS (www.igc.ethz.ch/GROMOS) (Scott *et al.*, 1999; Christen *et al.*, 2005), GROMACS (www.gromacs.org) (Berendsen *et al.* 1995; Lindahl *et al.*, 2001; Van der Spoel *et al.*, 2005), LAMMPS (lammps.sandia.gov) (Plimpton, 1995), NAMD (www.ks.uiuc.edu/Research/namd) (Nelson *et al.*, 1996; Kale *et al.*, 1999; Phillips *et al.*, 2005), and TINKER (dasher.wustl.edu/tinker).

8.2.1
Potential Energy Function

The potential energy function used in MD simulation includes several terms describing both internal (bonded) and external (nonbonded) interactions, which ultimately determine both structure and dynamics of a molecular system. The bonded terms are associated with the interactions between covalently bonded atoms separated by one, two, or three chemical bonds, whereas the nonbonded terms are associated with through-space electrostatic and van der Waals (vdW) interactions. The potential energy function used in the all-atom CHARMM empirical protein force field (MacKerell, 1998b), for example, is

$$
\begin{aligned}
U(\mathbf{R}) &= \sum_{\text{bonds}} K_b(b-b_0)^2 \\
&+ \sum_{\text{angles}} K_\theta(\theta-\theta_0)^2 \\
&+ \sum_{\text{dihedrals}} \sum_{n} K_\chi[1+\cos(n\chi-\delta)] \\
&+ \sum_{\substack{\text{nonbonded}\\ \text{pairs} i,j}} \left\{ \frac{q_i q_j}{4\pi\varepsilon_0 r_{ij}} \right. \\
&\left. + \varepsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{12} - 2\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{6}\right]\right\} \qquad (1)
\end{aligned}
$$

where we describe each term below. Once the potential energy of the system is calculated using Eq. (1), the forces on all atoms can be obtained from the first derivate with respect to atomic positions $\{R_i\}$ from which trajectories of atomic positions can be generated.

The bonded energy terms (first three terms in Eq. (1)) include harmonic terms associated with changes in bond length, b, (stretching) and bond angle, θ, (bending) with respect to their reference values (b_0 and θ_0) with stiffness governed by force constants (K_b and K_θ), as well as a series of cosine terms for rotation around a bond associated with the barrier height (K_χ), multiplicity (n), and phase angle δ to describe changes in the dihedral angle χ. Nonbonded interactions (last terms of Eq. (1)) are described by a simple Coulomb potential for electrostatic interactions between atomic partial charges q_i and q_j at a distance r_{ij}, with permittivity of free space, ε_0, employed due to the explicit nature of the simulated dielectric medium, as well as a Lennard-Jones (LJ) 6–12 potential for vdW interactions between atomic sites. In the representation used here, ε_{ij} is the depth of the vdW energy minimum and σ_{ij} is the position of that minimum (as opposed to the position of the zero of the potential energy used in other representations). The parameters in Eq. (1) are fitted to reproduce experimental and/or quantum mechanical reference data for a number of model systems (MacKerell, 2004). The quality of these parameters and associated target data are key factors that determine the accuracy of the empirical force field.

Parameterization is typically an iterative multistep procedure, which requires substantial computational resources (Foloppe and MacKerell, 2000; MacKerell, 2004). Because it is nearly impossible to perform parameterization for all atoms in each protein system of interest, the concept of "atom type" is introduced, which allows an easy transfer of the parameters developed for a limited set of model compounds to a much wider ranger of molecular systems: referred to as the "transferability" of the force field. Atoms belonging to a particular type typically share the same bonded and non-bonded parameters, even though they can belong to different molecules or even functional groups. The assignment of atom types ("typing") relies not only on atomic numbers, but also on their chemical environment (e.g. charge and hybridization state, hydrogen bonding potential, etc.) (MacKerell, 2004; Guvench and MacKerell, 2008). The larger number of atom types, in principle, provides a more accurate description of a molecular system but decreases force field transferability. Therefore, some compromise is sought, where several dozens of different atom types are used in modern biomolecular force fields.

Even though parameters in biomolecular force fields such as CHARMM or Amber are developed for specific residues, they can be used for modeling of other compounds with similar functional groups, allowing for simulations of protein complexes with different substrates, cofactors, inhibitors, and so on (Guvench and MacKerell, 2008). As a rule, force fields for different classes of biomolecules (proteins, nucleic acids, lipids, carbohydrates) can be used together, which allows simulations of proteins in lipid bilayers or protein–nucleic acid complexes, for example (Wang *et al.*, 2001; MacKerell and Nilsson, 2008; Sapay and Tieleman, 2008). For instance, the CHARMM protein force field (MacKerell, 1998b) can be used together with CHARMM lipid (Feller and MacKerell, 2000) and/or nucleic acid (Foloppe and MacKerell, 2000) force fields. There is also a trend toward the development of the more general force fields and software packages that allow automatic assignment of atomic types and partial atomic charges (e.g. the general Amber force field, GAFF) (Wang *et al.*, 2004).

The choice of model compounds is an important factor for force field development. They should be relatively small, representative of protein functional groups, and have available reference data. Beside model compounds, some test molecules should be selected that are not included during parameter optimization, but which can be used to test the accuracy and transferability of parameters (MacKerell, 1998). For instance, for protein backbone parameter development, *N*-methylacetamide

(NMA) is often used as a model compound since it contains important functional moiety, amide linkage, capped by methyl groups (MacKerell, 1998b; MacKerell, 1998). In addition, a large number of structural, vibrational, condensed-phase thermodynamic data are available for this compound, which makes it a good parameterization target (MacKerell, 1998). NMA is used for parameterization of nonbonded and some internal parameters, whereas a larger molecule, alanine dipeptide (ALAD) is commonly used for the optimization of backbone conformational properties (MacKerell, 1998b). MD simulations using other di- and tetrapeptides have been used for parameter validations. Parameters for each protein side chain are also obtained using side chain analogs, that is molecules having the same atoms as amino acid side chain truncated at C_α (for instance, acetamide for Asn, methyl indole for Trp) with some exceptions (MacKerell, 1998). The experimental and/or QM data for these model compounds are then used for parameter optimization.

8.2.2
Intramolecular Parameters

The mathematical forms for the terms in the empirical potential energy function usually represent a compromise between simplicity and accuracy (MacKerell, 2001). For instance, harmonic terms for bond stretching and angle bending are sufficiently accurate at ambient conditions. In some force fields, commonly used for small molecules, for example MMFF (Halgren, 1996), MM3 (Lii and Allinger, 1991), MM4 (Allinger *et al.*, 1996), QMFF (Ewig *et al.*, 2001), the bonded terms are expanded to include higher-order terms to account for anharmonicities and/or crossterms to take into account coupling of different bonded interactions. These force fields are termed Class II force fields, whereas biomolecular force field missing such terms are referred to as Class I force fields (Leach, 2001) In some potential energy functions, the Morse potential is used for bonds and cosine-based term applied for angles (Mayo *et al.*, 1990; Rappe *et al.*, 1992). These terms increase the force field accuracy for molecular geometries far from equilibrium structures but are usually not required for typical protein simulations. Equilibrium bond lengths and angles are parameterized on the basis of spectroscopic measurements, if available, or QM geometries of model compounds, whereas corresponding force constants are fitted to best reproduce experimental or QM gas-phase vibrational spectra (MacKerell, 1998; MacKerell, 2004).

For the dihedral energy term, a Fourier cosine series (Eq. (1)), with different values of multiplicity n (ranging from 1 to 6) corresponding phase angles χ, and force constants K_χ, are fitted to reproduce a QM potential energy surface (PES) corresponding to a rotation around given bond. This is especially important for protein force fields, where an accurate treatment of both backbone and side chain PES is critical for protein structure and dynamics. For instance, it was recently shown that, to different extents, standard CHARMM22, Amber, and OPLS-AA force fields do not provide sufficiently good agreement for the distribution of protein backbone ϕ and ψ dihedral angles compared to crystal structure and QM calculations (Hu *et al.*, 2003; MacKerell *et al.*, 2004). This deficiency manifested itself in the presence of an unrealistically large fraction of π-helical conformations in simulated proteins (Shirley and Brooks, 1997; Feig *et al.*, 2003). This led to revision of corresponding dihedral parameters for Amber (Wang *et al.*, 2000; Okur *et al.*, 2003) and OPLS (Kaminski *et al.*, 2001). In CHARMM a different approach was used: dihedral crossterms of grid-based energy correction maps (CMAP) were utilized to accurately reproduce a high-level PES for alanine, glycine, and proline dipeptides with subsequent empirical adjustments (MacKerell *et al.*, 2004; MacKerell, 2004). By using this approach, the agreement between CHARMM and experimental (PDB survey data) or QM/MM ϕ and ψ distributions in solution was substantially improved (MacKerell, 2004).

Two additional terms are present in the CHARMM potential energy function. The first one is a Urey-Bradley angular term (Urey and Bradley, 1931), which treats the 1–3 interaction by a harmonic potential depending on the distance between terminal atoms and helps reproduce more accurately reference vibrational spectra of model compounds (Guvench and MacKerell, 2008). The second term (also present in some other bimolecular force fields) is a separate improper dihedral energy term, treated in CHARMM with a harmonic potential similar to bond and angle terms. Such a term is used to maintain planarity of some functional groups (e.g. amide linkage in proteins) and can be used to improve the agreement with reference vibrational spectra. Improper torsion terms are also used in united atom force fields to prevent chiral center inversion during MD simulations (Leach, 2001). In these force fields, hydrogen atoms are treated as a part of non-H atoms, to which they are bonded, and thus the latter are called *united or extended atoms*. Most often such treatment applies to nonpolar H atoms only, whereas polar hydrogen atoms are still treated explicitly to properly describe hydrogen bonding interactions. Some (mostly earlier) versions of popular biomolecular force fields CHARMM19 (Neria *et al.*, 1996), Amber ff84 (Weiner *et al.*, 1984) and ff06 (Yang *et al.*, 2006), GROMOS87 and GROMOS96 (van Gunsteren *et al.*, 1996; Daura *et al.*, 1996; Daura *et al.*, 1998), and OPLS-UA (Jorgensen and Tiradorives, 1988) belong to the united atom force field category, whereas CHARMM22 (MacKerell, 1998b), OPLS-AA (Jorgensen *et al.*, 1996), and Amber ff95 (Cornell *et al.*, 1995) are all-atom force fields.

8.2.3
Nonbonded Parameters

The accurate treatment of nonbonded interactions is usually a key component of any biomolecular force field development because of the strong influence of the environment on protein properties (MacKerell, 2001). These interactions are not only limited to those between different molecules but also within large molecules between nonbonded atoms and can have an influence on the conformational energetics and to less extent molecular geometries and vibrational spectra (Guvench and MacKerell, 2008). The functional form used for nonbonded interactions, shown in Eq. (1) includes a Coulomb potential for electrostatics and a LJ 6–12 potential for vdW interactions, representing the combination of attractive dispersion forces and exchange electron repulsion. The implementation of an LJ potential may vary between different biomolecular force fields with the use of different combination rules and special treatment of 1–4 interactions. Combination rules are used to simplify LJ parameter development and are based on the assumption that parameters for cross-interactions between atom types i and j, ε_{ij} and σ_{ij}, can be obtained by some combination of parameters for types i and j. In CHARMM and Amber, Lorentz–Berthelot combining rules are used, where LJ well-depths are combined using geometric mean (the Berthelot rule) $\varepsilon_{ij} = \sqrt{\varepsilon_{ii}\varepsilon_{jj}}$ and interatomic separations using arithmetic mean (the Lorentz rule): $\sigma_{ij} = 0.5(\sigma_{ii} + \sigma_{jj})$ (MacKerell, 1998b; Guvench and MacKerell, 2008). Geometric means for both ε_{ij} and σ_{ij} are used in OPLS-AA and GROMOS force fields. The validity of using Lorentz–Berthelot combining rules in molecular simulations has been recently questioned, and the use of the more advanced Kong combining rules (Kong and Chakrabarty, 1973) has been suggested (Delhommelle and Millie, 2001).

Typically nonbonded interactions between atoms separated by one or two chemical bonds (1–2 and 1–3 interactions) are not included in atomistic force fields, whereas those for atoms separated by three bonds (1–4 interactions) are typically included, but might be scaled to differentiate from the rest of non-bonded interactions. This is motivated by the need to tune conformational energetics while keeping the same set of parameters for intra- and intermolecular interactions (Guvench and MacKerell, 2008).

In most biomolecular force fields, LJ parameters are obtained by reproducing condensed-phase properties such as densities or molecular volumes and heats of vaporization of neat liquids at ambient conditions (MacKerell, 2004): an approach pioneered during the development of the original OPLS force field (Jorgensen and Tiradorives, 1988). Alternatively, crystal parameters and heats of sublimation can be used as target properties (Warshel and Lifson, 1970; MacKerell *et al.*, 1995). The common problem encountered with the above approach is the so-called parameter correlation, where different sets of LJ parameters can reproduce the same condensed-phase properties (MacKerell, 2001). On the other hand, the direct application of QM data for LJ parameter optimization is difficult owing to the need for a very high level of theory and basis sets to properly account for dispersion interactions. To alleviate these problems the combined QM–empirical approach has been used where high-level *ab initio* data on model compound interaction with rare gas atoms were used in the LJ parameter optimization along with experimental pure solvent properties (Yin and Mackerell, 1998; Chen *et al.*, 2002).

Different approaches have been used in biomolecular force field for the determination of partial atomic charges. In Amber, charges for model compounds are obtained from the restrained fitting to QM electrostatic potentials (RESP) (Bayly *et al.*, 1993; Cieplak *et al.*, 1995). Hyperbolic restraints help reduce charges on buried atoms and remove some dependence on the molecular conformation (Leach, 2001). In Gromacs and OPLS, charges are empirically adjusted along with LJ parameters to reproduce condensed-phase properties. In the CHARMM force field, partial atomic charges are optimized to reproduce QM interaction energies (IEs) and geometries of model compounds with water (MacKerell, 1998b). Polarization effects not present in the empirical CHARMM force field functional form are included implicitly by choosing partial charges that overestimate gas-phase dipole moments (MacKerell, 2004). Therefore, reference QM IE are scaled up (by a factor of 1.16 for neutral models) and CHARMM minimum-energy interaction distances are kept shorter than their QM counterparts. This method allows balancing protein–protein, protein–water, and water–water interactions (Guvench and MacKerell, 2008).

Some empirical force fields also include an explicit hydrogen bonding term, which can be modeled, for example by 10–12 or 4–6 function similar to an LJ potential, but often direction dependent through the use of cosine factors (Goodford, 1985; Vedani, 1988). However, it was shown that the combination of Coulomb and LJ potentials can accurately reproduce nonbonded interactions between molecules including hydrogen-bonded interactions without the need for such a term (Reiher, 1985). If the hydrogen bond directionality is not reproduced well, it can be mimicked through the use of off-site charge distributions reminiscent of lone pairs (Dixon and Merz, 1997; Harder *et al.*, 2006). Recently, as a part of OPLS-AA force field revision, the off-plane charge model for aromatic rings was proposed, which better mimics their electronic configuration and provides more accurate tryptophan side chain hydration free energy as well as cation–π interactions (Xu *et al.*, 2007). The idea to use off-site charge distribution was also used in both early and more recent four- and five-site water models (Bernal and Fowler, 1933; Stillinger and Rahman, 1974; Jorgensen *et al.*, 1983; Mahoney and Jorgensen, 2000) (see below).

Comparison of experimental and calculated properties such as solvation free energies, dielectric constants, isothermal compressibilities, NMR relaxation times can be also used to test the quality of the developed force field parameters. For instance, testing of these properties was, for instance, an integral part of CHARMM alkane and ether parameter development (Yin and Mackerell, 1998; Klauda *et al.*, 2007; Vorobyov *et al.*, 2007). In general, agreement with experimental properties is reasonably good. However, many biomolecular force fields (CHARMM, Amber, OPLS) tend to underestimate hydration free energies of neutral amino acid side chain analogs (Shirts *et al.*, 2003; Deng and Roux, 2004). Solvation free energies have also been used as target data in some force fields such as OPLS and recent GROMOS versions. In GROMOS, for example, solvation-free energies in both water and cyclohexane were used as target data (Oostenbrink *et al.*, 2004). In principle, using target partitioning data for parameterization is a logical step in ensuring correct protein structures, in particular, for membrane proteins, which require separation of hydrophobic and hydrophilic residues (discussed in greater detail below). We note, however, that this is limited in the case of ionizable side chains, for which direct experimental measurement of charged species in nonpolar phases is lacking. However, indirect measures of solvation free energies can be obtained. For instance, using CHARMM, the free energy of a charged arginine (Arg) analog, methyl guanidinium, is accurately reproduced in water, but is severely underestimated in cyclohexane (Vorobyov *et al.*, 2008). This deficiency stems from incorrect dielectric constant of nonpolar substances, such as liquid hydrocarbons, which appear vacuum-like (dielectric constant of ~1), instead of the experimental value of ~2 (Vorobyov *et al.*, 2005; Vorobyov *et al.*, 2007) owing to the lack of explicit electronic polarizability. We now discuss recent attempts to incorporate electronic polarizability into force fields and return to the effect on amino acid solvation later in this chapter.

8.2.4
Polarizable Force Fields

Electrostatic interactions in biomolecular force fields are normally treated using fixed partial atomic charges interacting through Coulomb law. The electronic polarization is not explicitly included but treated implicitly through assignment of partial atomic charges overestimating gas-phase molecular dipole moments and IE to reproduce condensed-phase properties. Such force fields are commonly referred to as additive or non polarizable with CHARMM22 (MacKerell, 1998b), AMBER ff95 (Cornell *et al.*, 1995), OPLS-AA (Jorgensen *et al.*, 1996), and GROMOS96 being representatives. They provide a fairly accurate description of aqueous condensed-phase environments for protein simulations but cannot simultaneously provide accuracy for systems with distinctly different polarity, for example, gas phase or liquid hydrocarbon (MacKerell, 1998b; MacKerell, 2004). Empirical force fields, which explicitly include an electronic polarizability contribution, can provide a remedy for such deficiencies. Polarizability can be included in Eq. (1) as a separate term and/or modification of the Coulomb electrostatic term. Electronic polarizability can be introduced via point dipoles, fluctuating charges, classical Drude oscillators (shell), or a combination of those models. Comprehensive reviews of the different models are given elsewhere (Halgren and Damm, 2001; Rick and Stuart, 2002; Ponder and Case, 2003; MacKerell, 2004; Yu and van Gunsteren, 2005; Patel and Brooks, 2006; Warshel *et al.*, 2007).

In the point dipole moment model, explicit polarization is included in the form of induced dipoles assigned to polarizable atoms. This was the first approach to be applied for modeling polarization in biomolecular systems using the Langevin dipole model by Warshel and Levitt (1976). The induced dipole moment, $\boldsymbol{\mu}_i$, is proportional to the electric field $\mathbf{E}_i$, where the constant of proportionality, α_i, is the atomic polarizability, which can be considered as a force field parameter (Rick and Stuart, 2002; MacKerell, 2004). The electrostatic energy of a polarizable system includes an induction term:

$$U_{\text{ind}} = -\frac{1}{2}\sum_i \boldsymbol{\mu}_i \cdot \mathbf{E}_i^0 \tag{2}$$

where $\mathbf{E}_i^0$ is the electric field due to permanent charges (and dipoles, quadrupoles in some models (Ren and Ponder, 2003)). The expression for μ_i can be written as

$$\boldsymbol{\mu}_i = \alpha_i \left[\mathbf{E}_i^0 - \sum_{j \neq i} \mathrm{T}_{ij} \boldsymbol{\mu}_j \right] \tag{3}$$

where T_{ij} is the dipole field tensor describing interactions between induced dipoles i and j. Since each induced dipole feels the presence of other induced dipoles, their values can be obtained iteratively or through matrix inversion

(Rick and Stuart, 2002). The interactions between induced dipoles can be screened at short distances as was first suggested by Thole (1981) to avoid the "polarization catastrophe," that is infinite polarizability component as dipoles come closer than $(4\alpha_i\alpha_j)^{1/6}$) (Rick and Stuart, 2002; Yu and van Gunsteren, 2005). Alternatives to solve this problem include increasing vdW repulsion, reducing polarizabilities or spreading them over several centers, using a non linear dependence of $\boldsymbol{\mu}$ on the electric field (Yu and van Gunsteren, 2005).

In the fluctuating charge (FC) models (Rick and Stuart, 2002; Patel and Brooks, 2006) the partial atomic charges are not fixed but can redistribute between atoms in a molecule following the principle of electronegativity neutralization (Patel and Brooks, 2006). Such charge transfer depends on the atomic electronegativities (abilities to attract electrons), χ_i^0, and hardnesses (resistance to change the number of electrons, defined as one-half of the energy required to transfer electron from one atom to another), J_{ii} (Rick and Stuart, 2002; Patel and Brooks, 2006). Both χ_i^0 and J_{ii} are typically considered force field parameters to be optimized (Rick and Stuart, 2002). The electrostatic energy of an isolated molecule in this model can be represented by

$$U_{\text{elec}} = \frac{1}{4\pi\varepsilon_0}\left(\sum_i \chi_i^0 q_i + \frac{1}{2}\sum_i\sum_j q_i q_j J_{ij}(r_{ij})\right) \tag{4}$$

J_{ij} can be assigned to be simply $1/r_{ij}$ or some screening factor can be used. In most FC models, charges are allowed to fluctuate only within each molecule, so there is no intermolecular charge transfer, and interactions between atoms in different molecules are calculated through Coulomb law (Rick and Stuart, 2002). The values of atomic charges q_i are obtained iteratively by seeking the stationary point $\partial U_{\text{elec}}/\partial q_i = 0$ for atoms in the system, $i = 1, \ldots N$ under constraint of molecular charge preservation, which is equivalent to electronegativity neutralization within each molecule (Rick and Stuart, 2002; Patel and Brooks, 2006).

In the classical Drude oscillator model, auxiliary charged particles are attached to polarizable atoms via harmonic springs with a force constants, k_{Di}. The partial atomic charges, q_i, are distributed between the atomic core (c) and Drude particle (D): $q_i = q_{\text{ci}} + q_{\text{Di}}$. The magnitudes of q_{Di} can be obtained from atomic polarizabilities α_i as $q_{\text{Di}} = \sqrt{\alpha_i k_{Di}}$. In turn, values of α_i along with partial atomic charges q_i are force field parameters determined from restrained fitting to the QM electrostatic potential maps perturbed by background charges placed around a molecule (Anisimov *et al.*, 2005). The electrostatic potential term in the potential energy function is modified to include Coulomb interactions between atomic cores and Drude particles. The Coulomb interactions between Drude particles on atoms separated by one or two bonds (1–2 and 1–3) are included but smeared by using the exponential screening function similar to that used for point dipole models as proposed by Thole (1981). A harmonic term describing the self-energy of a polarizable atom $0.5k_{Di}d^2$ (where d is the displacement of the Drude particle from the atomic core) is included. The Drude force constant k_{Di} can be treated as a tensor, allowing for anisotropic polarizability (Harder *et al.*, 2006). The positions of Drude particles can be determined self-consistently under the Born–Oppenheimer approximation (Anisimov *et al.*, 2005).

The iterative nature of solutions for polarizable potentials, which needs to be applied at every time step of MD to find equilibrium values of induced dipoles, charges or Drude particle positions, make these calculations very time consuming compared to simulations using nonpolarizable force fields. The application of polarizable models to MD simulations of biomolecular systems was facilitated through the development of extended Lagrangian simulation protocols, where polarizable degrees of freedom were assigned small masses and propagated with atomic degrees of freedom (Rick *et al.*, 1994; Vanbelle *et al.*, 1992; Tuckerman and Martyna, 2000; Lamoureux and Roux, 2003). Polarizable force field development to date has concentrated much on water models (Barnes *et al.*, 1979; Caldwell *et al.*, 1990; Dang *et al.*, 1991; Vanbelle *et al.*, 1992; Rick *et al.*, 1994; Lamoureux *et al.*, 2003; Ren and Ponder, 2003; Yu and van Gunsteren, 2004; Lamoureux *et al.*, 2006) owing to its importance in biomolecular systems and as a simple test-case for methodology testing. We discuss water models in the following section and concentrate here on protein force fields.

While many early studies on polarizable protein force fields used scaled charges and other parameters from nonpolarizable models (Caldwell and Kollman, 1995a; Meng *et al.*, 1996; Wang *et al.*, 2000), a lot of efforts were made for a careful parameter development for model compounds, building blocks of proteins and other biomolecules, such as hydrocarbons (Vorobyov *et al.*, 2005; Patel and Brooks, 2006a; Lopes *et al.*, 2007), ethers (Hermida-Ramon and Rios, 2000; Borodin and Smith, 2006; Vorobyov *et al.*, 2007), alcohols (Gao *et al.*, 1995; Patel and Brooks, 2005a; Patel and Brooks, 2005; Anisimov *et al.*, 2007; Geerke and Van Gunsteren, 2007), aldehydes (Hermida-Ramon and Rios, 1998; Mannfors *et al.*, 2000), as well as amines and amides (Ding *et al.*, 1995; Meng *et al.*, 1996; Rick and Berne, 1996; Mannfors *et al.*, 2001; Xie, *et al.*, 2007; Harder *et al.*, 2008). The parameterization for NMA as a model for the protein backbone can be considered as one of the cornerstones of the polarizable protein force field development and has proven to be challenging (Patel and Brooks, 2004; Xie, *et al.*, 2007; Harder *et al.*, 2008). Protein force fields based on parameterization of a number of model compounds have been reported as well (Banks *et al.*, 1999; Stern *et al.*, 1999; Kaminski *et al.*, 2002; Palmo *et al.*, 2003; Ponder and Case, 2003; Kaminski *et al.*, 2004; Patel and Brooks, 2004; Donchev *et al.*, 2008).

MD simulations of proteins using polarizable protein force fields are still scarce but are rapidly emerging (Patel *et al.*, 2004; Harder *et al.*, 2005; Kim *et al.*, 2005; Maple *et al.*, 2005; Friesner, 2006; Friesner, 2006; Khoruzhii *et al.*, 2008; Jiao *et al.*, 2008; Masella *et al.*, 2008). Some earlier studies were performed either in the gas phase or using implicit solvent models (Banks *et al.*, 1999; Kaminski *et al.*, 2002), whereas peptide and protein polarizable MD simulations using explicit solvent representation have become more widespread (Liang and Walsh, 2007; Patel *et al.*, 2004; Harder *et al.*, 2005; Kim *et al.*, 2005; Jiao *et al.*, 2008; Khoruzhii *et al.*, 2008; Masella *et al.*, 2008). Polarization was found to have a substantial effect on solvent structure and dynamics near charged residues (Kim *et al.*, 2005)

In other calculations of protein–ligand binding energies using polarizable protein and solvent models have been performed (Maple *et al.*, 2005; Friesner, 2006; Khoruzhii *et al.*, 2008; Jiao *et al.*, 2008) with good agreement with experimental data (Khoruzhii *et al.*, 2008; Jiao *et al.*, 2008). Even though polarizable force fields might be considered superior to additive models, they might be not available for all systems of interest and might be harder to parameterize owing to larger number of parameters and a wider range of reference data aimed to be reproduced. In many cases nonpolarizable force models might be sufficient as shown later in this chapter. Polarizable force fields also have limitations and might not be able to reproduce polarizability limits (Giese and York, 2004), in which case QM or QM/MM approach might be a method of choice.

8.2.5
Water, Ion, and Lipid Models

Water is the dominant component of any biological system: its interaction with biomolecules determining their structure and dynamics. Therefore, the use of an accurate water model is crucial. The most widely used nonpolarizable water models in protein MD simulations, TIP3P (three-point transferable intermolecular potential) (Jorgensen *et al.*, 1983) and SPC (simple point charge) (Berendsen *et al.*, 1981) or simple point charge–extended (SPC–E) (Berendsen *et al.*, 1987), are rigid three-site water models. This means that there are three Coulomb/LJ interaction sites centered on O and H nuclei with fixed bond lengths and angle. These models have some differences in geometry (e.g. HOH angle of 104.52° for TIP3P and tetrahedral angle of 109.47° for SPC and SPC/E) as well as nonbonded parameters. In another popular TIP4P model, the site of negative charge is moved away from oxygen along the HOH bisector, which improves structure and properties compared to TIP3P (Jorgensen *et al.*, 1983). These models reproduce condensed-phase properties such as density, heat of vaporization and water structure well at ambient conditions are widely used in conjunction with biomolecular force fields. However, all water models have some limitations, for example too high diffusion coefficient, lack of long-range structure, or overestimation of bulk potential energy (MacKerell, 2004). There also exist five-site water models, such as ST2 (Stillinger and Rahman, 1974) and TIP5P (Mahoney and Jorgensen, 2000), where oxygen charge is distributed between two lone pair sites. The TIP5P water model was found to better reproduce experimental temperature-dependent properties (such as the density vs. temperature profile) and liquid water structure (Jorgensen and Tirado-Rives, 2005), at the expense of increased computational cost. Flexible water models, on the basis of SPC or TIP4P models, have also been reported (Ferguson, 1995; Lawrence and Skinner, 2003; Wu *et al.*, 2006), with improved dielectric constant, diffusion coefficient, and liquid-phase infrared spectra, for example. However, the use of such models is more computationally expensive and requires the use of a smaller time step for MD simulations.

A fundamental limitation of water models, mentioned earlier, is the lack of explicit electronic polarizability, because gas-phase properties had to be sacrificed to get accurate condensed-phase properties. In particular, the water dipole is expected to be quite different in the bulk liquid, around ionic species or in some hydrophobic environment, which is not possible in a non-polarizable model. Polarizable models can provide good agreement for a wide range of condensed-properties without sacrificing the gas-phase properties. Many polarizable water models are capable of reproducing both gas-phase (dipole moment, water cluster structure and energetics) and condensed-phase properties (molecular density, heat of vaporization, and dielectric constant). One example is the four-site SWM4-DP (simple water model with 4 sites and Drude polarizability) Drude polarizable water on the basis of the TIP4P geometry (Lamoureux *et al.*, 2003; Lamoureux *et al.*, 2006). This model was optimized to reproduce a wide range of gas-phase, condensed-phase, and interfacial properties (Lamoureux *et al.*, 2006). However, atomic polarizabilities need to be scaled down from their gas-phase values to reproduce condensed-phase properties (Alfredsson *et al.*, 1998; Halgren and Damm, 2001; Lamoureux *et al.*, 2003). The need for such reduction was attributed to the energy cost of the overlapping electron clouds opposing induction (Halgren and Damm, 2001; Lamoureux *et al.*, 2003; Anisimov *et al.*, 2005) Such polarizability scaling was also extended to other model compounds (Anisimov *et al.*, 2005; Vorobyov *et al.*, 2007; Anisimov *et al.*, 2007), although the choice of the appropriate scaling factors is still an open question.

This does not mean, though, that previous MD simulations using nonpolarizable potentials produced incorrect results. For instance, it was recently reported that the nonpolarizable TIP3P water model describes two extreme cases of ionic solvation in the bulk phase and in strongly anisotropic single file of water inside a narrow pore very similar to the Drude polarizable SWM4-DP water model (Allen *et al.*, 2004b). Nevertheless, polarizable models of water, and other solvents might provide better descriptions of their structural reorganization and dynamics around charged and polar species. Polarizable models also offer the possibility of describing ionization. For example, the dissociable water model PM6 consists of O^{2-} and H^{+} moieties (Stillinger and David, 1978) and has been used to study the mechanism of proton transfer along hydrogen-bonded chains of water molecules (Pomes and Roux, 1998) and to elucidate the proton blockage mechanism in aquaporins (Chakrabarti *et al.*, 2004).

In this review we focus our application on ion channels. The study of ion channels relies on a correct parameterization of metal and halide ion interactions with water and protein. Accurate polarizable models for ion solvation (Caldwell *et al.*, 1990; Dang *et al.*, 1991; Meng *et al.*, 1994; Stuart and Berne, 1996; Bryce *et al.*, 1998; Grossfield *et al.*, 2003; Lamoureux and Roux, 2006; Whitfield *et al.*, 2007; Warshel *et al.*, 2007; Warren and Patel, 2007), partitioning (Dang, 1999) and ion pair interactions (Shelley *et al.*, 1993; Soetens *et al.*, 1997) are also an active area of development. Polarizability has been found to be important for ion solvation energetics, ion-solvent distributions, binding to interfaces and ion pair interaction potentials (Halgren and Damm, 2001; Warshel *et al.*, 2007). It was also found that cation–π interactions, which are commonplace in protein structures (Dougherty, 1996; Crowley and Golovin, 2005), are more accurately described by polarizable force fields (Caldwell and Kollman, 1995b).

The development of accurate ion force field model is challenged by the absence of reliable experimental solvation data for ions in water and even more so in other solvents. Only hydration free energies of ion pairs and $\Delta\Delta G_{\mathrm{sol}}$ between same-charge ions (e.g. Na^+ and K^+) are known with certainty. The reported absolute solvation free energies of ions typically rely on some extrathermodynamic assumption regarding the magnitude of ΔG_{sol} for H^+ or OH^-. The solvent interfacial potential should be also taken into account while comparing different ion solvation free energy estimates and can account for observed differences (Lamoureux and Roux, 2006). Neutron diffraction data might provide another source of reference information. However, a radial distribution function (RDF) from diffraction studies may have peak positions only accurate to around ±0.05 to 0.1 Å. Such a leeway in σ of the LJ parameters can lead to variations in solvation energetics of the order of 10 kcal mol^{-1} (Allen *et al.*, 2006a). This almost "free" parameter requires other accurate experimental benchmark data to constrain its value, such as gas-phase interactions of ions with water molecules. However, in the framework of nonpolarizable force fields it has been a challenge to reproduce both gas phase interactions while at the same time reproducing solution phase solvation energetics (Berneche and Roux, 2001; Allen *et al.*, 2006b). This deficiency can be circumvented by using polarizable ion and solvent potentials (Grossfield *et al.*, 2003; Lamoureux and Roux, 2006; Warren and Patel, 2007). The consistent procedure for the parameter development for a series of alkali metal and halide ions in the framework of the classical Drude oscillator model on the basis of a wide range of experimental data has been reported recently (Lamoureux and Roux, 2006). The developed parameters were found to be consistent with a unique hydration free energy scale corresponding to the absolute intrinsic hydration free energy of proton of −247 kcal mol^{-1}, thus allowing an estimate of an important quantity not available from experiment (Lamoureux and Roux, 2006).

For membrane protein and especially ion channel MD simulations, an accurate description of ion solvation not only in water, but also liquid amides is of great importance, because an ion may leave the aqueous environment to be solvated by protein groups (Allen *et al.*, 2006b; Allen *et al.*, 2006a). In nonpolarizable CHARMM, the LJ interactions of ions with amides have been adjusted to reproduce either bulk solvation data or gas-phase interactions (Allen *et al.*, 2006b). Reasonable agreement for both ion gas-phase and condensed-phase energetics in water and formamide was demonstrated by a polarizable AMOEBA potential (Grossfield *et al.*, 2003). In a recent combined experimental and computational study, the Drude polarizable force field was found to provide a good agreement with ion–NMA gas-phase reference data as well as experimental ion solvation in liquid NMA, water, and partitioning between these solvents thus ensuring a proper balance of different interactions for ion channel MD simulations.

Lipid models are also essential for membrane protein MD simulations (Merz, 1997; MacKerell, 2004; Sapay and Tieleman, 2008; Klauda *et al.*, 2008). The development of accurate atomistic lipid models is challenging since at physiological conditions they are in the fluid-like liquid-crystalline state, which leads to a lack of experimental high-resolution structural data necessary for their careful parameterization. Careful optimization of parameters of lipid components such as hydrocarbon, phosphate, choline, glycerol, ether moieties are performed using model compounds, and then the derived lipid parameters are tested against experimental low-resolution X-ray, solid-state deuterium NMR, neutron diffraction data (MacKerell, 2004). The most commonly used lipid models used in atomistic MD simulations are those associated with CHARMM and GROMOS force fields. The phospholipid model available in CHARMM has been developed over the years to include parameters for saturated (Schlenkrich *et al.*, 1996; Feller and MacKerell, 2000; Klauda *et al.*, 2005; Klauda *et al.*, 2008), monounsaturated (Feller *et al.*, 1997), and polyunsaturated (Feller *et al.*, 2002) phosphatidylcholines (PC). Parameters for other lipid classes such as phosphatidylethanolamine and sterols (Cournia *et al.*, 2005) are also available in CHARMM (Klauda *et al.*, 2008) CHARMM lipid force field development was on the basis of reproduction of a range of experimental and high-level QM data and has undergone several revisions related to improvement of dihedral and nonbonded parameters (Feller and MacKerell, 2000; Klauda *et al.*, 2005; Klauda *et al.*, 2008). The latest version of this force field (CHARMM27R) was found to provide excellent agreement for a number of experimental parameters for lipid bilayers and monolayers such as structure factors, electron density profiles, deuterium order parameters, NMR spin lattice relaxation times, and translational diffusion constants (Klauda *et al.*, 2008). There were also considerable efforts toward the development of the GROMOS lipid force field and several models have emerged over the years (Berger *et al.*, 1997; Daura *et al.*, 1998; Chiu *et al.*, 1999a; Chiu *et al.*, 1999b; Chandrasekhar *et al.*, 2003). Parameters for other lipid classes (for example cholesterol (Baran and Mazerski, 2002), sphingomyelin (Chiu *et al.*, 2003), and phosphatidylserine (Mukhopadhyay *et al.*, 2004)) have also been developed. GROMOS lipid force fields are united atom models with zero charges on carbon atoms, thus allowing substantial speedup of MD simulation using these parameters.

One of the controversial issues related to lipid force field parameters is the surface area per lipid and appropriate value of surface tension during MD simulations. The area per lipid is a good structural parameter to check force field quality. However, experimental values are available only for a few bilayers and their values are subject to uncertainties (Nagle and Tristram-Nagle, 2000). Nevertheless, MD simulations of lipid bilayers using constant experimentally determined surface area are commonplace. MD simulations of dipalmiotylphosphatidylcholine (DPPC) lipid bilayers using the latest CHARMM force field produce nonzero surface tension (20 dyn/cm per leaflet for systems consisting of 72 lipids) when simulated at experimental surface area (Klauda *et al.*, 2008). This result is in disagreement with experimental data on macroscopic lipid films and vesicles indicating nearly zero surface tension (Tien and Diana, 1968; Israelachvili *et al.*, 1977; Jahnig, 1996). The reason for such a discrepancy is still under contention (Klauda *et al.*, 2008). However, the nonzero surface tension may be related to the relatively small size of the membrane patch used in MD simulations (Feller and Pastor, 1999; Klauda *et al.*, 2008). Undulations, known to occur in macroscopic membranes, might balance the positive surface tension for small membrane patches, not sampled by atomistic MD simulations (Klauda *et al.*, 2008). Alternatively, MD simulations at constant surface area producing nonzero surface tension maybe considered (Feller and Pastor, 1999; Klauda *et al.*, 2008). However, in the popular GROMACS force field implementation by Berger *et al.* (1997), the positive surface tension was chosen to be corrected by reducing lipid head group charges. A similar approach was used in a recent attempt to modify CHARMM lipid force field by Sonne *et al.* (2007). Such modifications might, however, result in the loss of balance of different lipid–lipid, lipid–solvent, and lipid–protein interactions.

Lipid bilayers exhibit dipole potentials that arise from a nonuniform distribution of charge at their interfaces. These positive potentials create extra barriers for cation permeation. The dipole potential can be determined from MD simulation by double integration of charge density using Poisson's equation (Lamoureux *et al.*, 2003). Experimental estimates for lipid bilayers are available from freeze-fracture experiments (cryo-electron microscopy) (Wang *et al.*, 2006a), or the partitioning of large hydrophobic ions (Clarke, 2001). These estimates indicate that for saturated PC bilayers the dipole potential should be on the order of 200–500 mV (Clarke, 2001; Wang *et al.*, 2006a). However, MD simulations of these lipids in CHARMM, GROMOS, and other nonpolarizable force fields typically produce dipole potential values higher than experimental estimates (e.g. 850 mV for CHARMM27R) (Wang *et al.*, 2006a; Klauda *et al.*, 2008). This discrepancy can be corrected by using a polarizable force field. Our preliminary studies indicate that the use of Drude polarizable force field parameters for lipid hydrocarbon tails alone results in a dipole potential consistent with experiment while maintaining the correct lipid geometry and order (unpublished results).

8.2.6
Coarse-Grained Force Fields

CG force fields treat a group of atoms and/or molecules as a single particle or interaction site. The united atom approximation described earlier can be considered as a limiting type of CG approach. There are even methods where the whole protein is modeled as one or few CG particles (Tozzini, 2005). Typically, simplified (and "softer") potential energy functions are used in CG force fields allowing a substantial increase in MD time step. These methods can provide a speedup of several orders of magnitude and can be used to study phenomena occurring on much larger time and length scales. Protein CG force fields have been devised for the variety of applications (Tozzini, 2005) including refinement of low-resolution structures (Delarue and Dumas, 2004), normal mode analyses (Tama *et al.*, 2002; Bahar and Rader, 2005), studies of protein folding (Levitt and Warshel, 1975; Go and Taketomi, 1978; Miyazawa and Jernigan, 1985; Liwo *et al.*, 1997; Liwo *et al.*, 2005; Maupetit *et al.*, 2007), large-scale motions of proteins and macromolecular assemblies (Trylska *et al.*, 2005; Tozzini and McCammon, 2005; Arkhipov *et al.*, 2006a), and membrane-associated protein and peptide simulations (Venturoli *et al.*, 2005; Smeijers *et al.*, 2006).

CG lipid models are also needed for membrane protein simulations. A number of CG models of lipid membranes have been reported (see Goetz and Lipowsky, 1998; Shelley *et al.*, 2001; Stevens *et al.*, 2003; Marrink *et al.*, 2004; Murtola *et al.*, 2004; Orsi *et al.*, 2008 or Venturoli *et al.*, 2006; Muller *et al.*, 2006; Ayton *et al.*, 2008 for recent reviews). One of the popular lipid CG models by Marrink *et al.* (2004) has been recently adapted for simulations of membrane associated peptides and proteins (Shih *et al.*, 2006; Bond and Sansom, 2006; Bond *et al.*, 2007; Bond and Sansom, 2007; Scott *et al.*, 2008). This model is based on approximately 4-to-1 mapping of nonhydrogen atoms to one CG particle and a gain up to 3–4 orders of magnitude in the computational efficiency compared to atomistic simulations (Marrink *et al.*, 2004), while maintaining reasonable agreement with experimental structural, dynamical and thermodynamic data for model compounds (Marrink *et al.*, 2004; Baron *et al.*, 2007), and lipid assemblies (Marrink *et al.*, 2004).

This model has been applied to study lipid bilayer insertion for a number of membrane proteins providing good agreement with atomistic simulations and experimental data (Bond and Sansom, 2006; Bond *et al.*, 2007; Scott *et al.*, 2008; Sansom *et al.*, 2008). This CG model has been used to model the membrane insertion of the S4 helix and entire voltage sensor domain of the voltage-gated K^+ channel KvAP (Bond and Sansom, 2007). The S4 peptide contains multiple Arg side chains, but was shown to exhibit almost equal preference to adopt membrane-spanning or interfacially bound orientations (Bond and Sansom, 2007). This suggests little penalty for exposing charged Arg to lipid hydrocarbon in sharp contrast to atomistic simulations (Dorairaj and Allen, 2007; Li *et al.*, 2008a). Such discrepancy was found to originate from an incorrect physical representation of charged side chain interactions with solvent and lipids in this CG model, since interaction and partitioning free energies are an order of magnitude smaller than those from atomistic simulations. This leads to underestimation of free energy barriers for Arg translocations across lipid bilayers (Vorobyov *et al.*, 2008). A more detailed description of atomistic simulations for charged side chain translocation across lipid bilayers is provided in Section 8.5.2. The revised version of this force field, called MARTINI, has more CG particle types and improved parameters to approximately reproduce experimental partitioning free energies between polar and nonpolar media for a large number of model compounds (Marrink *et al.*, 2007) achieved good agreement with atomistic simulations, although some discrepancies for charged residues still persist (Monticelli *et al.*, 2008). This revised force field has been used, for example, in MD simulations of mechanosensitive (Yelimov *et al.*, 2008) and voltage-gated potassium channels (Treptow *et al.*, 2008).

Another approach is multiscale coarse-graining (MS-CG) method of Voth and co workers relying on force-matching from atomistic MD simulations (Izvekov and Voth, 2005; Noid *et al.*, 2008a; Noid *et al.*, 2008b). This methodology was successfully applied to simulations of the gramicidin A (gA) ion channel in a hydrated lipid bilayer, where the protein was modeled by atomistic force field whereas lipid and water molecules were described using CG representation (Shi *et al.*, 2006). The use of such methods, which allows resolution exchange between CG and atomistic representations (Ayton *et al.*, 2007), might extend applicability of CG simulations and increase their accuracy (Monticelli *et al.*, 2008).

8.3
Molecular Dynamics Method for Protein Systems

Here we discuss the basic methods for carrying out MD simulations of protein systems. More detailed reviews can be found elsewhere (Allen and Tildesley, 1987; Frenkel and Smit, 2002; Leach, 2001; Vangunsteren and Berendsen, 1990; Becker *et al.*, 2001; Rapaport, 2004; Adcock and McCammon, 2006). MD involves the numerical solution of Newton's equation of motion $F = ma$. First, positions and velocities are assigned to all atoms from experimental data (e.g. crystal or NMR structure), minimized geometry or a previous MD simulation. Initial velocities are usually assigned based on a Maxwell–Boltzmann distribution for a given temperature. Forces, F, acting on every particle, and thus accelerations, $a = F/m$, are calculated from gradients of the potential energy: $F = -\nabla U(\mathbf{r})$. Numerical integration algorithms are based on Taylor series expansion of atomic positions in time and can be derived using the Liouville operator formalism (Tuckerman *et al.*, 1992). The Verlet algorithm (Verlet, 1967) expresses position at the next time step $r(t + \Delta t)$ in terms of the previous and current positions ($r(t - \Delta t)$ and $r(t)$) and acceleration $a(t)$ through a difference of Taylor expansions forward and backward in time, eliminating the need to keep track of velocities which are then estimated via finite differences (FDs). The leap-frog algorithm (Hockney, 1970), instead calculates velocities at half-integer time steps (i.e. $v(t - \Delta t/2)$ and $v(t + \Delta t/2)$) and uses them to calculate new positions $r(t + \Delta t)$. In this algorithm, however, particle positions and their velocities are not calculated at the same time, therefore it is impossible to directly compute total energy at a point in time. The velocity Verlet integrator (Swope *et al.*, 1982), more commonly used in biomolecular simulations today, also explicitly incorporates velocity into equations of motion but calculates positions and velocities for a given time step from their values at previous time step as well as accelerations at current and previous time steps: $r(t + \Delta t) = r(t) + v(t)\Delta t + (1/2)a(t)\Delta t^2$ and $v(t + \Delta t) = v(t) + (1/2)(a(t) + a(t + \Delta t))\Delta t$. All these schemes should, in principle, lead to the same trajectories. There also exist algorithms in which higher-order derivatives of the particle coordinates are involved, such as the predictor–corrector algorithm (Gear, 1971). Such methods are more computationally expensive but can allow longer time steps (Leach, 2001). The most important criteria to be considered while choosing an integrator are the conservation of energy and momentum, time reversibility and ability to use longer time steps (Allen and Tildesley, 1987; Frenkel and Smit, 2002).

In all MD algorithms there are numerical errors, revealed by root mean square (RMS) energy fluctuations. Since the error depends on the time step, Δt, with smaller values not only providing better accuracy, but also limiting phase space sampling. Therefore, some compromise is sought to provide numerical stability as well as reasonable trajectory length. Δt is, however, limited by the fastest molecular motions. For instance, the vibration of a C–H bond is ~10 fs and thus requires the use of ~1-fs time step.To use longer time steps, the bond lengths can be fixed at equilibrium values. In CHARMM protein simulations, all bonds involving hydrogens are fixed with holonomic constraints using the SHAKE algorithm (Ryckaert *et al.*, 1977), in which a system of nonlinear constraint equations is solved using a method of Lagrange multipliers. A similar algorithm called Rattle (Andersen, 1983) is used in a new CHARMM velocity Verlet integrator (Lamoureux and Roux, 2003). The SETTLE algorithm (Miyamoto and Kollman, 1992), which solves for three constraints at a time, can be used to constrain the geometry of rigid water molecules. Another algorithm called LINCS (linear constraint solver) (Hess *et al.*, 1997) was reported to be several times faster than SHAKE and is used in GROMACS simulations to constrain all bond lengths (not just those involving hydrogen). An alternative approach for imposing rigidity is the use of the equations of motion in terms of the quaternions (Evans and Murad, 1977; Allen and Tildesley, 1987; Miller *et al.*, 2002): though this is seldom used in present-day simulations. All such constraint algorithms allow one to increase the time step during MD runs of biomolecular systems to 2 fs or more (Feenstra *et al.*, 1999). An alternative approach is to use multiple time steps for different atomic motions in the system (Streett *et al.*, 1978; Tuckerman *et al.*, 1992; Martyna *et al.*, 1996).

8.3.1
Approximations to Handle Finite Systems

The molecular system will have a finite size that is limited to 10^3–10^6 atoms with present-day computational resources. However, this creates artificial boundary effects. One approach to alleviate these effects is to impose periodic boundary conditions (PBC), in which a system is replicated in three dimensions to provide an infinite periodic lattice. In the MD simulation, once the particle leaves the primary cell in one direction, it would enter from the opposite direction (a process called *image centering*) (Allen and Tildesley, 1987; Leach, 2001). The distance between two atoms i and that in the closest image j is considered to be the minimum image distance (Darden, 2001). The use of PBC has drawbacks, however. For instance, it inhibits fluctuations of the particles in the systems with wavelengths greater than the size of the box (Allen and Tildesley, 1987).

For the simplest cubic or orthorhombic cell, 26 nearest neighbor image cells are present. Depending on the molecular system being modeled, different shapes of the primary cell can be used. For instance, for simulations of roughly spherical proteins it is desirable to limit the number of solvent molecules by using a truncated octahedron or rhombic dodecahedron cell (Allen and Tildesley, 1987; Leach, 2001). For simulations of oriented proteins or proteins elongated in one dimension (e.g. proteins embedded into lipid bilayers), it is sometimes desirable to use hexagonal periodic boundaries (Allen *et al.*, 2003a; Dorairaj and Allen, 2007). The simplest and most widely used space group used in MD simulation is P1, where unit cells are replicated only by translation. It is possible, however, to use different crystal symmetry operations, such as inversions and screw axes, to impose symmetry that may assist in maintaining desired system properties. For instance, $P2_1$ allows, for example, lipid molecules to switch leaflets in membrane simulations while maintaining chirality (Dolan *et al.*, 2002).

An alternative to PBC is to use an implicit representation of the protein environment (e.g. solvent and/or lipid membrane). The interactions with the environment can be modeled in an average way on the basis of some effective potential. In this case the dynamics of the system is typically described by Langevin equation of motion to take into account random collisions with the solvent molecules via a random force, $R(t)$, and a frictional drag, γ (Allen and Tildesley, 1987; Roux *et al.*, 2004):

$$m_i a_i(t) = F_i(t) - \gamma_i v_i(t) m_i + R_i(t) \tag{5}$$

The value of γ is typically in the range 5–100 ps^{-1} (Feig, 2008). If γ_i is large, the inertial term $m_i a_i(t)$ can be neglected resulting in Brownian dynamics (BD) (Roux *et al.*, 2004).

Electrostatic interactions between solute and solvent can be obtained by solving the Poisson–Boltzmann (PB) equation (Sharp and Honig, 1990; Fogolari *et al.*, 2002; Roux *et al.*, 2004), which is a modification of the Poisson equation in the presence of mobile ions. The Poisson equation is the second-order differential equation, relates the variation in the electrostatic potential ϕ with the charge density ρ in the medium with given spatially varying dielectric response $\varepsilon(\mathbf{r})$ (Jackson, 1999)

$$\nabla\varepsilon(\mathbf{r})\nabla\phi(\mathbf{r}) = -\rho(\mathbf{r})/\varepsilon_0 \tag{6}$$

If mobile ions are present, the term describing Boltzmann distribution of these ions is added giving rise to the PB equation, which in the linear form (first-order truncation of a Taylor series expansion of $\sinh[\phi(\mathbf{r})]$) can be written as:

$$\nabla\varepsilon(\mathbf{r})\nabla\phi(\mathbf{r}) - \kappa^2(\mathbf{r})\phi(\mathbf{r}) = -\rho(\mathbf{r})/\varepsilon_0 \tag{7}$$

where κ is the Debye–Hückel screening factor (Feig, 2008). The PB equation can be solved to obtain ϕ, from which the electrostatic contribution to solvation free energy, $\Delta G_{\text{solv, elec}}$, can be obtained (Roux *et al.*, 2004; Feig, 2008).

To perform MD simulations, gradients in $\Delta G_{\text{solv, elec}}$ must be calculated (Feig, 2008). Yet, analytical solutions to the PB equation are available only for a handful of simple boundary conditions (plane, sphere, infinite cylinder, toroid), leading to the need for numerical solutions using approaches such as the boundary element (Zauhar and Morgan, 1985; Rashin, 1990; Zhou, 1993; Vorobjev and Scheraga, 1997; Bordner and Huber, 2003), finite element method (Orttung, 1977; You and Harvey, 1993; Cortis and Friesner, 1997; Holst *et al.*, 2000; Baker *et al.*, 2000) or most commonly used FD method (Warwicker and Watson, 1982; Klapper *et al.*, 1986; Gilson and Honig, 1987; Davis and McCammon, 1989; Holst and Saied, 1995). In the finite difference approach, the solution is usually performed using a cubic lattice, which is superimposed onto the molecular system with each grid point assigned values of ρ, ε, ϕ and screening factor κ. The values of ρ are obtained from the distribution of partial atomic charges over the adjacent grid points, whereas the values of ε are assigned on the basis of the solute–solvent boundary (Darden, 2001). Atomic radii for determination of this solute-solvent boundary are typically parameterized to reproduce solvation free energies of model compounds (Sitkoff *et al.*, 1994; Nina *et al.*, 1997). The boundary can be defined as either molecular (vdW) surface or (more accurately) as solvent-accessible surface by rolling a molecular probe (hard sphere representing water or other solvent moiety, e.g. CH_2 for lipid tails) (Allen *et al.*, 2004a). Partial atomic charges can be also assigned using similar fitting (Sitkoff *et al.*, 1994) or can be taken from an atomistic force field (Nina *et al.*, 1997). Numerical approaches to solve the PB equation have been implemented in several software packages such as DelPhi (Klapper *et al.*, 1986; Gilson and Honig, 1987), UHBD (Davis *et al.*, 1991), APBS (Baker *et al.*, 2001), and CHARMM (Nina *et al.*, 1997; Im *et al.*, 1998).

PB-based methods have been applied not only to the modeling of aqueous protein solvation but also to modeling of lipids and proteins in a hydrated lipid bilayer environment using implicit membrane models (Murray *et al.*, 1997; BenTal *et al.*, 1996; Kessel *et al.*, 2000; Roux *et al.*, 2000; Im and Roux, 2002). In these models the interior of the membrane is modeled as a hydrocarbon-like slab with ε of 1 or 2 and the exterior as water-like with ε of 80. The contribution from the transmembrane (TM) potential originating from a small charge imbalance near the membrane–solution interfaces can be accounted for by a modified PB (PB-V) equation (Roux, 1999; Roux *et al.*, 2004).

In practice, combination of PB with MD is problematic as the PB equation would need to be solved iteratively every time step (Luo *et al.*, 2002; Lu *et al.*, 2002; Prabhu *et al.*, 2004), and may suffer from large fluctuations (Feig, 2008). However, numerical PB methods can be also useful in post-simulation analysis, for example to examine electrostatic potentials in the molecular system (Honig and Nicholls, 1995; Jo *et al.*, 2008) or estimate periodicity artifacts (Hunenberger and McCammon, 1999a; Hunenberger and McCammon, 1999b; Allen *et al.*, 2006b). The diffusional trajectories of ionic species can be also computed by PB methods using BD (Fogolari *et al.*, 2002; Roux *et al.*, 2004), which has been applied to study ion conduction through biological pores (Allen *et al.*, 2000; Im *et al.*, 2001; Im and Roux, 2002; Noskov *et al.*, 2004).

An alternative approach for the calculation of $\Delta G_{\mathrm{solv,\,elec}}$ using an implicit solvent representation is the generalized Born (GB) approximation (Still *et al.*, 1990). This phenomenological model is the generalization of the Coulomb interaction (Warshel and Papazyan, 1998) that incorporates Born solvation energetics (Born, 1920) for an atom with charge q and radius a in the medium with the dielectric constant ε, for which

$$\Delta G^{\mathrm{Born}}_{\mathrm{solv,\,elec}} = -\frac{1}{8\pi\varepsilon_0}\left(1-\frac{1}{\varepsilon}\right)\frac{q^2}{a} \tag{8}$$

In the GB model, $\Delta G_{\mathrm{solv,\,elec}}$, for collection of N atoms with charges q_i with Born radii a_i, can be written as:

$$\Delta G^{\mathrm{GB}}_{\mathrm{solv,\,elec}} = -\frac{1}{8\pi\varepsilon_0}\left(1-\frac{1}{\varepsilon}\right)\sum_{i,j=1}^{N}\frac{q_i q_j}{f_{ij}} \tag{9}$$

where f_{ij} depends on distance between atoms i and j, r_{ij} and Born radii (Still *et al.*, 1990): $f_{ij} = \sqrt{r_{ij}^2 + a_i a_j e^{-r_{ij}^2/(4a_i a_j)}}$.

The advantage of the GB method is that it is reasonably accurate and provides analytical derivatives (Feig *et al.*, 2004; Feig, 2008), thus allowing fast MD simulations. Various GB models (Schaefer and Karplus, 1996; Dominy and Brooks, 1999; Onufriev *et al.*, 2000; Lee *et al.*, 2003; Onufriev *et al.*, 2004) have been used to perform simulations of proteins in solution (Calimet *et al.*, 2001; Onufriev *et al.*, 2004; Fan *et al.*, 2005; Chocholousova and Feig, 2006; Geney *et al.*, 2006), as well as implicit membrane models (Spassov *et al.*, 2002; Im *et al.*, 2003; Tanizaki and Feig, 2005). They are typically two-dielectric membrane models with $\varepsilon = 1$ implicitly assumed inside the membrane slab and $\varepsilon = 80$ everywhere else, although multiple dielectric layer models exist (Feig, 2008). In addition to the electrostatic contribution to solvation free energy, non-polar terms are also important components of the implicit solvation or membrane models. They include such contributions as the cost of the cavity formation and solute–solvent vdW interaction term, which are typically combined into one equation: $\Delta G_{\text{solv, nonp}} = \gamma A + b$, where A is the total solvent accessible surface area (SASA) of the solute, γ and b are empirical constants with b often assigned to be 0. Values of γ and b are often determined from the fitting to some reference (experimental or calculated from all-atom simulations) solvation or partitioning free energies for nonpolar compounds (alkanes, molecular oxygen) (Leach, 2001; Feig, 2008). For implicit membrane simulations lateral forces owing to membrane deformation upon molecule insertion into a bilayer can be also incorporated through an anisotropic contribution to $\Delta G_{\text{solv, nonp}}$ (Feig, 2008).

There are other implicit solvation approaches, which can be used for protein simulations. For instance, in the Langevin dipole method (Warshel and Levitt, 1976), the solute beyond its SASA is surrounded by a three-dimensional grid of rotatable point solvent dipoles with the size and direction determined iteratively using the Langevin equation. This methodology has been also applied to membrane protein modeling (Alden *et al.*, 1995; Grossfield *et al.*, 2000).

An alternative is to include a limited number of solvent molecules around the solute and represent the rest of them with an effective solvent boundary potential. One of the first implementations of this formalism was stochastic boundary condition method (Berkowitz and Mc Cammon, 1982), in which the system is divided into three spherical regions, such as a central reaction, a buffer, and the outermost static reservoir regions. As the solute moves, the corresponding regions move through the simulation box as well. The atoms in the reservoir region are typically kept fixed but exert forces on other regions in the system. Other mixed implicit/explicit schemes have been devised over the years (see (Roux, 2001) for review). A different approach called spherical solvent boundary potential (SSBP) (Beglov and Roux, 1994) which is based on the separation of the multidimensional solute–solvent configurational integral in terms of "inner" (closest to solute) and "outer" solvent molecules. The solute and a finite number of "inner" explicit solvent molecules are confined inside the hard sphere of a variable radius (to include the most distant "inner" solvent molecules), which fluctuates during MD simulation at constant pressure (Beglov and Roux, 1994; Roux, 2001). It was shown that SSBP gives amino acid analog solvation free energies in good agreement with those obtained using more computationally expensive PBC calculations (Deng and Roux, 2004). Furthermore, ion solvation free energies are fairly insensitive to the number of explicit water molecules (Beglov and Roux, 1994) and agree well with PBC results when adjusted for the value of the interfacial potential (Lamoureux *et al.*, 2006). SSBP has been applied to simulations of various biomolecular systems (Im *et al.*, 2001). There might also some artifacts associated with artificial structure and dynamics of solvent near the boundary and the assumption that there is isotropic bulk liquid beyond the boundary sphere (Darden, 2001).

The extension of the SSBP methodology to macromolecular systems with arbitrary geometries is the generalized solvent boundary potential (GSBP) method (Im *et al.*, 2001). A small part of the biomolecular system is represented in atomic detail, whereas the influence of remaining distant atoms is modeled with an effective boundary potential. In the GSBP approach, contributions from distant atoms are represented as solvent-shielded static field and a solvent-induced reaction field (Im *et al.*, 2001; Banavali *et al.*, 2002). These terms are invariant to atom configurations in the inner region and thus are calculated only once using FD PB equation. It was found that GSBP can provide accurate estimates of electrostatic free energy contributions in biomolecular systems at relatively low computational cost (Im *et al.*, 2001; Banavali *et al.*, 2002). GSBP has been used for simulations of biological systems mainly for calculations of protein–ligand binding free energies (Banavali *et al.*, 2002; Wang *et al.*, 2006b; Deng and Roux, 2006).

8.3.2
Maintaining Ensembles

We seek to compute average properties of our system, as well as thermodynamics, from the partition function in a given ensemble. In the absence of any treatment of the interaction with the surroundings, the equations of motion used in MD will produce microcanonical (*NVE*) ensemble (i.e. maintain constant number of particles N, volume V, and energy E). Such constraints are not typically used in real-world experiments and the fixed energy represents a significant constraint on phase space. It is therefore desirable to have a computational approach to sample from the canonical, *NVT* (constant N, V, and T) or isothermal–isobaric, *NPT* (constant N, P, and T) ensembles (McQuarrie, 2000). In the canonical ensemble the configurational integral of the partition function has the form

$$Z = \int d^{3N}\mathbf{R}\, e^{-U(\mathbf{R})/kT} \tag{10}$$

This allows computation of any average property $\mathcal{X}(\mathbf{R})$ that is a function of molecular configuration $\mathbf{R}$,

$$\langle \mathcal{X} \rangle_{(NVT)} = \frac{\int d^{3N}\mathbf{R}\, \mathcal{X}(\mathbf{R})\, e^{-U(\mathbf{R})/kT}}{\int d^{3N}\mathbf{R}\, e^{-U(\mathbf{R})/kT}} \tag{11}$$

and the configurational contribution to the Helmholtz free energy (defined to within a constant)

$$A = -kTlnZ \tag{12}$$

In the *NPT* ensemble this takes the form

$$\Delta^{\text{config}} = \int dV \int d^{3N}\mathbf{R}\, e^{-U(\mathbf{R})/kT} e^{-pV/kT} \tag{13}$$

$$\langle \mathcal{X} \rangle_{\text{NPT}} = \frac{1}{\Delta^{\text{config}}} \int dV \int d^{3N}\mathbf{R}\, \mathcal{X}(\mathbf{R}) \times e^{-U(\mathbf{R})/kT} e^{-pV/kT} \tag{14}$$

(identical to $\langle \mathcal{X} \rangle_{(NVT)}$ in the limit of infinite system size) and the configurational contribution to the Gibbs free energy (defined to within a constant)

$$G = -kT \ln \Delta^{\text{config}} \tag{15}$$

A seemingly simple approach to maintain constant temperature is to perform velocity rescaling at every time step by a factor of $(T_{\text{required}}/T_{\text{current}})^{1/2}$, the so-called isothermal MD (Woodcock, 1971), excluding temperature fluctuations altogether. In a more general approach, proposed by Berendsen (Berendsen *et al.*, 1984), the system is coupled to an external heat reservoir maintained at a certain temperature. The heat flow from the reservoir is then used to maintain the temperature of the system around the required value. The rate of temperature change is determined by a coupling parameter τ. Typically, the value of τ used in atomistic MD simulations with 1- to 2-fs timestep is on the order of 0.1 ps (i.e. around every 100 time steps), which corresponds to weak coupling. If τ is equal to the time step, this method is equivalent to a simple velocity rescaling. A problem associated with these methods is that they do not generate thermodynamic averages corresponding to *NVT*, *NPT* or any other known ensemble (Leach, 2001; Frenkel and Smit, 2002). The application of the weak coupling scheme to multicomponent systems (e.g. protein in the solvated lipid bilayer) may also result in artifacts, where the temperatures of components differ substantially while preserving the desired temperature for the whole system (the so-called hot solvent–cold solute problem). One method commonly used to circumvent this problem is to use multiple thermostats for different parts of the system, but this can also introduce artifacts (Lingenheil *et al.*, 2008). In an alternative approach, the system coupling to the external heat bath is achieved through stochastic collisions which act on randomly selected particles (Andersen, 1980). Between collisions the system evolves in the *NVE* ensemble. The strength of coupling is determined by the frequency of collisions. Even though this method generates canonical distribution and provides good results for time-independent properties, dynamic properties depend on the collision frequency (Frenkel and Smit, 2002).

Instead, extended system methods, first introduced by Nosé (1984) and Hoover (1985) are more commonly used today. In this approach, a thermal reservoir is considered as an integral part of the system and treated as an additional degree of freedom with coordinate s, with conjugate momentum p_s, in the equations of motion. Therefore, these methods can be considered as an application of extended Lagrangian methodology to temperature control (Frenkel and Smit, 2002). The temperature fluctuations in the system are controlled by a coupling parameter Q, which can be considered as the fictitious mass of the heat reservoir. A small value of Q results in rapid temperature fluctuations and vice versa. The application of the Nosé–Hoover algorithm to MD simulations results in a correct canonical distribution if there is only one conserved quantity (i.e. total energy of the extended system) or the center of mass (COM) of the system remains fixed in the absence of external forces (Frenkel and Smit, 2002). For a more detailed description of different methods used for constant temperature simulations, see the textbooks (Allen and Tildesley, 1987; Leach, 2001; Frenkel and Smit, 2002 and reviews Becker and Watanabe, 2001; Hunenberger, 2005).

In many cases, simulations at constant pressure P are more representative of systems studied experimentally and can alleviate artifacts from a predefined boundary dimension. Therefore, the temperature control should be combined with a pressure control algorithm, in which case the volume becomes the fluctuating variable (instead of the pressure). In the extended system approach (Andersen, 1980), coupling of the system to a piston is introduced via a coordinate ε, with conjugate momentum p_ε, and some fictitious mass parameter W. The value of W for this barostat defines the decay time for volume fluctuations (Becker and Watanabe, 2001). This method was later extended to non-cubic simulation cells and to allow non-isotropic pressure coupling (Parrinello and Rahman, 1980; Parrinello and Rahman, 1981; Nose and Klein, 1983). The drawback of this method is that the dynamics of the system might depend on the piston mass (Feller *et al.*, 1995a). In an alternative approach, the system can be coupled to a "pressure bath," with coupling constant τ_p that is inversely proportional to the rate of the pressure change (Berendsen *et al.*, 1984). The simulation box volume is rescaled by a factor γ, which corresponds to atomic coordinate rescaling by $\gamma^{1/3}$ for isotropic coupling. As for the temperature control weak coupling scheme, this method does not produce trajectories corresponding to any known ensemble (Allen and Tildesley, 1987; Becker and Watanabe, 2001), but allows for the damping of large volume fluctuations and is well suited for the equilibration stage of MD runs (Anezo *et al.*, 2003). The Langevin piston method developed by Feller *et al.* (1995a) resolves difficulties associated with the extended system and weak coupling methods of pressure control. In this method, the motion of the piston is described by a Langevin equation (Eq. (5)) with a collision frequency γ, eliminating the unphysical volume fluctuations related to the piston mass (Feller *et al.*, 1995b).

Sometimes it is necessary to use anisotropic pressure coupling for protein MD simulations, especially for those involving interfacial systems (for example proteins associated with hydrated lipid bilayers), possibly involving a surface tension γ (not to be confused with the coupling constants described earlier) at the interface (Zhang *et al.*, 1995). γ for a system with interface oriented with its normal in the z direction can be calculated from the diagonal components of the pressure tensor as

$$\gamma = 0.5 < L_z[P_{zz} - 0.5(P_{xx} + P_{yy})] \tag{16}$$

where L_z is the height of the cell, and the first factor 0.5 takes into account the presence of two interfaces in a simulation cell (Zhang *et al.*, 1995; Klauda *et al.*, 2008). For interfacial systems MD runs using constant normal pressure P_N and fixed surface area A (NP_NAT ensemble) or constant surface tension γ ($NP_N\gamma T$) are commonly used (Zhang *et al.*, 1995; Feller *et al.*, 1995b; Feller *et al.*, 1997; Feller and Pastor, 1999; Klauda *et al.*, 2008). Membrane-protein simulations using $NP_N\gamma T$ ensemble are complicated by the uncertainty in the appropriate reference value of γ for lipid bilayers (Feller and Pastor, 1999; Klauda *et al.*, 2008), leading to the frequent use of NP_NAT simulations instead. The area is set on the basis of the experimental surface area per lipid and the estimated projected surface area of the membrane proteins or peptide (Woolf and Roux, 1994; Berneche *et al.*, 1998).

8.3.3
Approximating Long-Ranged Forces

The majority of computer time in MD simulations of biomolecular systems is spent on the calculation of nonbonded forces, with the required time scaling as the square of the number of atoms in the system, $O(N^2)$ for a pairwise-additive potential energy function. If PBC are used and interactions between atoms in the primary cell and all image cells are counted, the number of nonbonded terms, which needs to be calculated becomes infinite. Therefore the minimum image convention is used, where the nonbonded potential is truncated to include interactions with the nearest images only, thus including only $(1/2)N(N-1)$ terms (Allen and Tildesley, 1987). However, even this approximation can be prohibitively expensive for large biomolecular systems comprising of tens of thousands of atoms. To reduce this computational cost, spherical cutoffs can be used, where the interactions between pairs of atoms further than some cutoff distance r_c are set to 0. The cutoff distance should be large enough to ensure a small effect owing to truncation, but not larger than half of the box length so as to maintain the minimum image convention. Cutoffs on the order of 12 Å are typically used. To determine, which atoms are located within this cutoff, nonbonded neighbor lists (Verlet, 1967) are generated. These lists are updated at regular intervals (e.g. every 10–100 steps) or using some heuristic algorithm to test for the movement of atoms in the system (Frenkel and Smit, 2002). For very large systems (with $L \gg r_c$) the cell index method for the nonbonded list updates can be used, where the simulation box is divided into cells with length longer than r_c (Leach, 2001; Frenkel and Smit, 2002). To expedite the handling of nonbonded interactions it is sometimes advantageous to use group-based cutoffs, where a molecule is divided into one or several groups consisting of a few atoms. These groups are often made electroneutral if possible, which eliminates long-range charge–charge and charge–dipole interactions (with energy varying as $1/r$ and $1/r^2$, respectively) between these groups and only dipole–dipole (energy varying as $1/r^3$) and higher-order terms surviving. It has been shown, however, that the use of group-based cutoffs can also lead to artifacts such as free rotation of polar groups just outside the cutoff distance (Darden, 2001; Steinbach and Brooks, 1994).

A common problem with both atom- and group-based cutoffs is that they produce discontinuities in both energies and forces at the cutoff boundary, r_c (Leach, 2001). To eliminate this problem, the potential can be modified to gradually reduce energies and/or forces to 0 at r_c. One approach is to shift the potential by adding a term, such that $U(r_c) = 0$. Alternatively, the force maybe shifted by adding a term to the potential to ensure $dU(r_c)/dr = 0$. The shifted potential or force is therefore modified even for $r < r_c$, with artifacts. An alternative is to apply a switching function, $S(r)$ (varying from 1 to 0), that can be used to gradually move the potential from $U(r_s)$ at some switching distance, r_s ($r_s < r_c$, to 0 at r_c). The modified potential then has the form $U'(r) = U(r)S(r)$. Typically in protein MD simulations, the value of r_s is set to be ~ 2 Å smaller than r_c to avoid rapid variation in force over short distances (Steinbach and Brooks, 1994). In the force switching method, the force (instead of the potential) is switched and the potential energy is then obtained by integrating the switched force between r_s and r_c with the constant term added to potential at $r < r_s$ to ensure its continuity at r_s, and was shown to lead to stable MD simulations (Steinbach and Brooks, 1994).

The use of finite cutoffs necessarily leads to the omission of some nonbonded interactions that may affect the accuracy of simulation results. The inclusion of contributions beyond cutoffs can be achieved in several ways. One of the simplest methods is to use two nonbond cutoffs: a "short" cutoff (e.g. 10 Å) where interactions are computed every time step, and a "long" cutoff (e.g. 30 Å) where interactions are computed more seldomly (such as at nonbond list update) It has been demonstrated that such twin-range cutoffs perform well for membrane simulations (Anezo *et al.*, 2003). Long-range corrections to the energy and pressure can then be estimated assuming a uniform distribution of atoms for $r > r_c$ (Allen and Tildesley, 1987), applied during or after simulations (Lague *et al.*, 2004) These corrections are relatively small (but still nonnegligible) for LJ interactions since they are short-ranged ($\sim 1/r^6$). However, for electrostatic interactions, which decay as $1/r$, these corrections are more significant. With such long-ranged interactions the use of any cutoff-based scheme and/or minimum image convention can cause artifacts (Allen and Tildesley, 1987; Feller *et al.*, 1996), which have been observed in simulations of biomolecular systems leading to solvent ordering (Anezo *et al.*, 2003).

One approach to circumvent the artifacts of truncated long-ranged interactions is to employ lattice methods, such as Ewald summation (Ewald, 1921), widely used in MD simulations today. In this approach, electrostatic interactions of a charged atom with all of its periodic images are calculated. The sum of these interactions is conditionally convergent, yet when converted into a sum of two series, convergence can be achieved (Leach, 2001). Each charge is surrounded by the neutralizing (i.e. of the same magnitude and opposite sign) Gaussian distribution $\rho_i(r) = q_i\kappa^3 \exp(-\kappa^2 r^2)/\pi^{3/2}$ where r is the distance from the center of this distribution and the parameter κ determines the width of this distribution. The interactions between the charges, plus their neutralizing distributions, (called the *real-space sum*) are now short-ranged and converge rapidly with distance (Allen and Tildesley, 1987). To obtain only the potential owing to the original charges, a second, canceling distribution is then added, with contributions summed, for simplicity in reciprocal space. A correction term, which accounts for the interaction of the neutralizing distribution with itself, is also added (Allen and Tildesley, 1987). The Ewald method is computationally expensive and scales as poorly as N^2 (Darden, 2001). To speed up calculations of the computationally demanding reciprocal sum term, several methods have been proposed. In the particle-mesh Ewald (PME) (Darden *et al.*, 1993; Essmann *et al.*, 1995) and related methods (Hockney and Eastwood, 1988; Luty *et al.*, 1994; Deserno and Holm, 1998), the point charges are interpolated to grid points (e.g. using B-spline interpolation), which is followed by the calculation of reciprocal-space sum using a fast Fourier transform (FFT). These methods scale as $N \log N$ and subsequently are used in most simulations of protein systems today (MacKerell, 2004).

Ewald summation also has artifacts originating from the imposed PBC, which become more pronounced for systems with low-dielectric solvent, small system size, nonzero net charge or large dipole (Hummer *et al.*, 1996; Smith and Pettitt, 1996; Darden, 2001; Anezo *et al.*, 2003). One such artifact is the nearly zero net force between charges separated by half of the box length (Smith and Pettitt, 1996; Leach, 2001). For periodic systems with nonzero net charge, a uniform charge distribution with the same magnitude and opposite sign (“neutralizing plasma”) is added to avoid divergence (Hummer *et al.*, 1996; Bogusz *et al.*, 1998; Darden, 2001). However, spurious interaction of atomic charges with this neutralizing distribution leads to artifacts in both energies and forces, which need to be corrected (Bogusz *et al.*, 1998). For solvated systems with net charge, there is also an artifact associated with perturbation of solvent molecules by periodic copies of a charged solute (Hunenberger and McCammon, 1999b). Both of these artifacts might be quite large (several kilocalories per mole) but often substantially cancel each other for polar systems (Bogusz *et al.*, 1998; Hunenberger and McCammon, 1999b; Warren and Patel, 2007) and can be estimated using continuum electrostatics (Hunenberger and McCammon, 1999a; Hunenberger and McCammon, 1999b).

An alternative approach for the treatment of long-range electrostatic interactions is the reaction field (RF) method (Allen and Tildesley, 1987; Tironi *et al.*, 1995; Leach, 2001). In this approach, interactions between atoms within some cutoff are treated explicitly, whereas interactions with those outside are modeled approximately via a continuous dielectric continuum. (Barker and Watts, 1973). While this might be a reasonable approximation for bulk liquids, it may fail for many heterogeneous biomolecular systems. Another approach is to treat distant interactions approximately using a multipolar expansion of the electrostatic potential (Darden, 2001). In cell multipole methods the simulation space is divided into cubic cells, for which multipole moments (charge, dipole, and quadrupole) are calculated. Then the interactions of atoms in a given cell with all adjacent cells are calculated explicitly, but with atoms in nonadjacent cells approximated using a multipolar expansion (Leach, 2001; Darden, 2001). With more distant atoms grouped into larger cells this method can be fairly efficient without substantial loss in the accuracy

(Leach, 2001; Darden, 2001), which inspired the development of more efficient $O(N)$ tree-based methods such as fast multipole algorithm (FMA) (Greengard and Rokhlin, 1987).

8.4
Calculation of Observables for Protein Structure and Function

MD trajectories maybe utilized in different ways: (i) to study the time evolution of structure, dynamics, interactions and correlations of a thermally fluctuating system and visualize microscopic phenomena; (ii) to sample phase space for the calculation of ensemble averaged equilibrium observables and the thermodynamics governing microscopic processes; and (iii) to force the system to ensure sampling or observation of a process of interest that may otherwise not occur in a reasonable simulation timeframe. Here we summarize some of the basic approaches used for these three kinds of studies.

8.4.1
Time Series and Average Properties

MD trajectories contain snapshots of the molecular system, coordinates (and velocities), sampled with a predefined sampling interval, $\Delta\tau$, typically much larger than the time step Δt. The optimal value of $\Delta\tau$ is determined on the basis of the timescale of the phenomenon under investigation. In atomistic protein simulations sampling is typically every 100 –1000 steps (i.e. $\Delta\tau$ are 0.2–2 ps using Δt of 2 fs). Calculations of some time-dependent property $\mathcal{X}$ that is a function of system coordinates and/or velocities for frames of the trajectory produce a time series $\mathcal{X}(t)$. Energy components, volume, temperature, pressure, and so on, are typically reported by a MD simulation program during the run. Time series using instantaneous values of $\mathcal{X}(t)$ tend to be noisy but can be smoothed by using block or running averages. Time series of energy, volume, IE between system components are useful in monitoring convergence of MD simulations. The root mean square deviation or displacement (RMSD) from some reference or initial structure can also be used for such monitoring (Biggin and Bond, 2008; Lindahl and Sansom, 2008). The RMSD is defined as

$$\mathrm{RMSD}(t) = \sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(\mathbf{r}_{i,(t)} - \mathbf{r}_{i,0}\right)^2} \tag{17}$$

where $\mathbf{r}_i(t)$ and $\mathbf{r}_{i,0}$ are coordinates of atom i for current and reference structure, preoriented by some prescription (Leach, 2001). The RMSD for different parts of the molecular system, for example C_α atoms of the protein (Biggin and Bond, 2008; Lei and Duan, 2008), can be calculated to monitor changes in protein structure and simulation convergence. In principle any scalar, vector, or tensor quantity maybe expressed as a time series from MD simulation. Once this time series is obtained it can be used for statistical analysis.

8.4.1.1 Averages and Correlations

The statistical analysis of MD simulation data is also an important part of data processing. It may involve calculation of averages, fluctuations, variances and covariances, higher order moments, and correlation functions. Some of these properties are briefly reviewed here, a more general and comprehensive description can be found elsewhere (Allen and Tildesley, 1987; Leach, 2001; Becker and Watanabe, 2001; Frenkel and Smit, 2002).

Time averages of $\mathcal{X}(t)$ can be obtained as

$$\bar{\mathcal{X}} = \frac{1}{\tau}\sum_{t=1}^{\tau}\mathcal{X}(t) \tag{18}$$

where τ is the simulation length or number of frames in the MD run (Allen and Tildesley, 1987; Frenkel and Smit, 2002). It is assumed that for sufficiently long MD run the time average of some property of the system is the same as its average over the statistical ensemble if the system is ergodic ($\langle\mathcal{X}\rangle = \bar{\mathcal{X}}$) (Frenkel and Smit, 2002). Therefore we can use all principles of ensembles in statistical mechanics on the basis of time averages.

An ensemble average of a quantity $\mathcal{X}$ which is function of atomic coordinates can be computed using Eq. (14) in the NPT ensemble. Such mean values can be structural (e.g. RDFs, correlations, NMR order parameters), dynamical (e.g. translational and rotational diffusion), or mechanical (e.g. elastic moduli) and each adds to our understanding of the origins of microscopic behavior. It is often necessary to look not at just single average values of some properties from MD simulations but at their distributions, binned into histograms. For example, the RDF, or $g_{ij}(r)$ is a pair distribution function, which describes probability of finding a particle i (atom, set of atoms, molecule, etc.) a distance r from another particle compared to the distribution in the homogeneous system with the same density (Allen and Tildesley, 1987).

$$g_{\alpha\beta}(r) = \frac{N_\beta(r, r+\delta r)}{4\pi r^2 \delta r \rho_\beta} \tag{19}$$

where $N_\beta(r, r+\delta r)$ is the number of atoms of species β between a distance r and $r+\delta r$ around an atom of species α with bulk reference density ρ_β. For neat liquids, $g(r)$ is a useful source of structural information and can be compared with experimental diffraction data (Leach, 2001). The integration of the unnormalized $g_{ij}(r)$ from 0 to r provides number of coordinating species inside a sphere with radius r. Coordination numbers can be calculated at the position of the first minimum in the $g(r)$ to obtain the number of species inside the first solvation shell (Li *et al.*, 2008a). Thus these numbers provide valuable structural information about protein surroundings. Moreover, by integration of the product of $g_{ij}(r)$ and another pair function $a_{ij}(r)$ the ensemble average $\langle a_{ij}\rangle$ is obtained, which can be used for calculating thermodynamic quantities such energy, pressure, and chemical potential (Allen and Tildesley, 1987).

To shed more light on function, it is usually essential to analyze interactions between different parts of the system not only in terms of distributions (e.g. RDFs), but also in terms of IEs (interaction energies) which offer a more quantitative description of interactions and their contributions to the governing thermodynamics of a process. An IE can be calculated simply as the difference in energies of a combined system (complex) and two interacting species, or simply as a sum of interactions between atomic paris. Statistical analysis of IEs can be used to identify the most relevant interactions to protein structure and function. If one is interested in a measure of "packing" of solvent around a solute or protein, then it maybe preferable to turn to measures other than energies that are less chemically specific. For instance, packing scores can be defined as (Grossfield *et al.*, 2006)

$$s = \sum_i \sum_j \frac{1}{r_{ij}^6} \tag{20}$$

(analogous to the attractive part of the LJ potential and related to the rate of magnetization transfer in NMR) and have been used to explore locations of specific protein–lipid interactions (Grossfield *et al.*, 2006).

Another important quantity that can reveal much about the interplay between components of a biological system is the covariance $\langle \delta A \delta B \rangle$ where δA, δB are fluctuations (e.g. $\delta A = A- < A >$). For instance, in a recent study of the signal-transduction mechanism in rhodopsin, the covariance between IEs of two pairs of protein residues has been calculated to determine how tightly they are coupled (Kong and Karplus, 2007). Time correlation functions between properties A and B are defined as (Allen and Tildesley, 1987; Leach, 2001; Becker and Watanabe, 2001)

$$C_{AB}(t) = \langle A(0)B(t) \rangle = \lim_{T\to\infty} \frac{1}{T-t} \times \int_0^{T-t} d\tau A(\tau)B(t+\tau) \tag{21}$$

If $A = B$ then quantity is called the *autocorrelation function* which reveals how a quantity is related to itself at some point later in time. The integral of the autocorrelation function $C_A(t)$ from 0 to ∞ is called *correlation* or relaxation time (Allen and Tildesley, 1987) and can be viewed as time taken to lose correlation (Leach, 2001). For instance, rotational correlation for water molecules can be determined by analyzing the decay of the dipole autocorrelation (Allen *et al.*, 1999) as a measure of rotational diffusion. One may also express correlations in space (as opposed to time) to determine a correlation length between two propertieis (e.g. the positions or orientations of molecules in space). The MD simulation time should be much longer than the correlation time of the slowest process of interest in the system, whereas the size of the system greater than the correlation length.

8.4.1.2 **Protein and Solvent Fluctuations**

Besides RMSD, root mean square fluctuations (RMSF) of protein residue coordinates with respect to their time-averaged values can also be calculated as

$$\mathrm{RMSF} = \sqrt{\frac{1}{\tau_{\mathrm{run}}} \sum_{t=1}^{\tau_{\mathrm{run}}} (\mathbf{r}(t) - \langle \mathbf{r}(t) \rangle_t)^2} \tag{22}$$

RMSF describe protein flexibility and can be related to 3D thermal (B) factors ($B = \frac{8\pi^2}{3} RMSF^2$) (Willis and Pryor, 1975) measured by X-ray crystallography.

The protein structure fluctuations are often hard to interpret owing to the complexity of motions in a large biomolecular system. However, it is possible to discern major collective modes of fluctuations using quasi-normal mode or principal component analysis (PCA) (Garcia, 1992; Amadei *et al.*, 1993; Kitao *et al.*, 1991). This method is based on the diagonalization of the covariance matrix of protein atom fluctuations. The principal modes with the largest eigenvalues corresponding to their contribution to the total fluctuation are identified, and the resultant eigenvectors for protein motions can be determined (Hess, 2000; Hayward and de Groot, 2008).The principal modes with the largest amplitude typically represent the slowest protein motions. In many cases they can be linked to function (Hayward and de Groot, 2008). Thus protein dynamics in the subspace of these modes is termed *essential dynamics* (Amadei *et al.*, 1993). The results of such analysis can be used for advanced sampling techniques such as conformational flooding (Grubmuller, 1995) and essential dynamics sampling (Amadei *et al.*, 1996). Thus, the PCA is a powerful tool for both analysis and simulations of large collective motions in proteins (Kitao and Go, 1999; Hayward and de Groot, 2008). It should be noted, however, that the timescale of modern MD simulations might be not long enough to sample these modes properly (Hess, 2000).

To examine the dynamics of solvent, the 3D diffusion coefficient, D, can be computed by mean square displacement (MSD) analysis via the relation

$$D = \lim_{t\to\infty} \frac{1}{6t} \left\langle |\mathbf{r}_i(t) - \mathbf{r}_i(0)|^2 \right\rangle \qquad (23)$$

which can be derived from the Langevin equation of Eq. (5), in the absence of a systematic force, F, and provides a prescription for the friction coefficient, γ and thus diffusion, $D = kT/m\gamma$ (Allen and Tildesley, 1987). If PBC are used, the effect of image centering and changes in the box dimensions need to be removed from trajectories to calculate the diffusion coefficient using Eq. (23). Moreover, calculation of D from 23 does not normally come from analysis of a single trajectory, but of all trajectories with every possible origin of time, by sliding an analysis window along the MD trajectory (Rapaport, 2004). One may also extract the following relationship from the Langevin equation in terms of the velocity (McQuarrie, 2000)

$$D = \frac{1}{3} \int_0^\infty \langle \boldsymbol{v}(0) \cdot \boldsymbol{v}(t) \rangle dt \qquad (24)$$

(in simplified notation for a correlation integral such as in Eq. (21))
where the diffusion coefficient comes from the velocity autocorrelation. One may also extract diffusion from the fluctuation–dissipation theorem by analyzing the force autocorrelation

$$D = \frac{3(kT)^2}{\displaystyle\int_0^\infty \langle \mathbf{R}(0)\mathbf{R}(t) \rangle dt} \qquad (25)$$

One concern when computing diffusion is the need to separate random and systematic forces, as Eqs. (23) and (24) were derived in the absence of systematic forces and Eq. (25) reveals that it is only the random contribution to the force that determines D. In some cases, incorrect values of D may be obtained. For example, if a particle is trapped in a deep energy well it is still diffusing despite its RMSD being small. One way to overcome this is to "clamp" the particle and measure the random forces at that fixed position using Eq. (25) (Mamonov *et al.*, 2006). Another, more theoretically complicated approach, is based on analysis of the Laplace transform of the velocity autocorrelation function on the basis of the generalized Langevin equation for a harmonic oscillator (Crouzy *et al.*, 1994). This approach is very useful for analysis of umbrella sampling biased trajectories to be described below. The following function is evaluated

$$D(z) = \lim_{s\to 0} \frac{-\hat{C}(s;z)\langle\delta z^2\rangle_{(i)}\langle\dot{z}^2\rangle_{(i)}}{\hat{C}(s;z)\left[s\langle\delta z^2\rangle_{(i)} + \langle\dot{z}^2\rangle_{(i)}/s\right] - \langle\delta z^2\rangle_{(i)}\langle\dot{z}^2\rangle_{(i)}} \tag{26}$$

where $C(t;z)$ is the velocity autocorrelation function for position z, and $\hat{C}(s;z)$ is its Laplace transform. To estimate the value of the limit as $s \to 0$, linear extrapolation is needed owing to a divergence. However, the above analysis is in fact equivalent to a real-space analysis derived by Hummer and coworkers that circumvents such extrapolation (Yeh and Hummer, 2004). We now have methods to extract measure of diffusion that are needed for calculations of rates of translocation, such as through aqueous solution and ion channels (Section 8.5.1).

8.4.2
Free Energy Calculation

A quantitative calculation of free energies is very important problem in computational biology (Brooks *et al.*, 1988; Kollman, 1993; Simonson, 2001; Meirovitch, 2007). Here we describe two main approaches to free energy calculation, potential of mean force (PMF), and alchemical mutation, and then venture into some more detailed approaches to extract microscopic mechanisms of protein function from MD simulations.

8.4.2.1 Potential of Mean Force Calculation

Many studies simulate for long periods and hope to observe a process of interest. This hit and miss approach does not make the best use of computational resources, nor it is reliable as outcomes can depend on initial configurations. The obvious difficulty of all-atom MD is that the trajectory of a large number of atoms must be computed, even though only a few coordinates maybe truly relevant to function. Rather than trying to observe rare events with "brute force" simulation, a better approach is to calculate a free energy landscape, characterized by identified "relevant" coordinates. One may project out the uninteresting degrees of freedom (i.e. integrate over them) to study the most relevant coordinates (Zwanzig, 2001; Mori, 1965), under the action of a mean force that is an average over the thermal fluctuations of the other $3N - 1$ degrees of freedom, $\mathbf{R}$ (Roux *et al.*, 2004). The PMF, W, is the thermodynamic reversible work along a chosen coordinate z, relative to some reference value z':

$$W(z) = -\int_{z'}^{z} d\zeta\, \langle F(\zeta)\rangle \tag{27}$$

or, in differential form the mean force is

$$\langle F(z)\rangle = -\frac{dW(z)}{dz} \tag{28}$$

where $F(z)$ is the instantaneous force acting on the chosen coordinate, z, with integration variable, ζ. One can easily show that the derivative of the following expression, that relates the free energy to a configurational integral, leads to the same mean force

$$W(z) = -kT\ln \times \left(\int d^{3N-1}\mathbf{R}\, e^{-U(z,\mathbf{R})/kT}\right) + \mathrm{C} \tag{29}$$

which by setting the free energy at some reference point, z' to zero the constant C maybe evaluated such that

$$W(z) = -kT \ln \left(\frac{\int d^{3N-1}\mathbf{R}\, e^{-U(z,\mathbf{R})/kT}}{\int d^{3N-1}\mathbf{R}\, e^{-U(z',\mathbf{R})/kT}} \right)$$

$$= -kT \ln \frac{\langle \rho(z) \rangle}{\langle \rho(z') \rangle} \qquad (30)$$

This ratio of configurational integrals therefore also determines the PMF. The ratio of configurational integrals also equals the relative density at z and z' and thus the equilibrium constant for the process of changing that degree of freedom from a value z' to a value z. Thus, by computing average density along the reaction coordinate one knows the free energy change, and thus the reversible work involved in moving along the reaction coordinate. PMF calculations entail simulating long enough so that all interesting values of the relevant coordinates are encountered, and an equilibrium distribution of uninteresting coordinates are integrated over. However, in many cases it is difficult to sample all values of the relevant coordinates, simply because they correspond to the rate limiting steps and thus usually involve significant free energy barriers; not thermally accessible in a manageable simulation timeframe. To assist, one may apply some biasing potentials to ensure sampling of all interesting values of z. For example, in the method of Umbrella Sampling (Torrie and Valleau, 1977), a series of biasing potentials, as simple as harmonics, $w_i(z) = \frac{1}{2}K_i\,(z - z_i)^2$, maybe added to the system potential, $U(z, \mathbf{R})$, in a series of separate simulations/ "windows," i. Because it is known how the coordinate, z, was biased, it is possible to remove this bias postsimulation. Trajectories may be combined and rigorously unbiased with the weighted histogram analysis method (WHAM) (Kumar *et al.*, 1992). In this method one uses the biased histograms to solve for the optimal estimate for the unbiased density, ρ, and thus the PMF using Eq. (30) above.

$$\langle \rho(z) \rangle = \frac{\sum_{i=1}^{N} n_i \,\langle \rho(z) \rangle_{(i)}^{\text{bias}}}{\sum_{i=1}^{N} n_i e^{-[w_i(z)-F_i]/kT}} \qquad (31)$$

where N is the number of WHAM windows and n_i is the number of independent data points. Free energy constants F_i can be determined using the optimal estimate for the distribution function:

$$e^{-F_i/kT} = \int dz\, e^{-w_i(z)/kT} \,\langle \rho(z) \rangle \qquad (32)$$

Alternatively one may simply compute the mean force from these simulations directly, or simply use the magnitude of the constraint force (which is equal and opposite to the instantaneous force on the reaction coordinate) to obtain the PMF via integration.

8.4.2.2 **Free Energy Perturbation**

Free energy perturbation (FEP) calculations are popular in biomolecular simulation because of their ability to explore reaction coordinates other than spatial coordinates. In particular, alchemical transformations such as single site mutations of key residues associated with protein folding and function

(Funahashi *et al.*, 2003; Park and Lee, 2005; Pan and Daggett, 2001; Wang *et al.*, 1998), ion mutations to explore ion selectivity of ion channels (Allen *et al.*, 1999; Allen *et al.*, 2000; Luzhkov and Aqvist, 2001; Berneche and Roux, 2002; Noskov *et al.*, 2005), and protonation states of titratable groups in proteins (Merz, 1991; Simonson *et al.*, 2004; Yoo and Cui, 2008) can be sampled at equilibrium. The procedure involves introducing a thermodynamic coupling parameter λ, varying from 0 to 1, to transform between an unperturbed, $U(\lambda = 0)$, and some perturbed, $U(\lambda = 1)$, potential energy function of the system (Kollman, 1993)

$$U(\lambda) = \lambda U(\lambda = 1) + (1 - \lambda) U(\lambda = 0) \tag{33}$$

The free energy difference, ΔG, can be computed via free energy perturbation (Zwanzig, 1954; Kollman, 1993)

$$\Delta G = -kT \times \sum_{\lambda=0}^{1} \ln \left\langle \exp\left[-\frac{U(\lambda + \Delta\lambda) - U(\lambda)}{kT} \right] \right\rangle_{(\lambda)} \tag{34}$$

or, equivalently, via thermodynamic integration (TI) (Kirkwood, 1935)

$$\Delta G = \int_0^1 d\lambda \left\langle \frac{\partial U}{\partial \lambda} \right\rangle_{(\lambda)} \tag{35}$$

where the subscript (λ) signifies that ensemble averaging has been carried out for that particular value of the scaling parameter. In reality a finite number of scaling parameters are used. However, if the magnitude of the perturbation is great then the distribution of configurations at one value of λ and the next will be very different. To ensure good convergence of the free energy, one should typically ensure that entropic changes remain within a couple of kT units between windows (Lu *et al.*, 2003) One may also employ non-linear scaling to avoid rapid changes at a given λ value (Shirts *et al.*, 2003). Analysis of FEP simulations may also be improved through a WHAM analysis since the free energy contribution for a given value of λ is computed using all information from the simulation in an optimal way (Souaille and Roux, 2001).

A problem may occur in solvation free energy calculations that arises from the linear coupling scheme for the vdW energy term upon "particle annihilation." At the end point of the FEP simulation as, $\lambda \to 0$, there is a singularity owing to the repulsive portion of LJ potential (Simonson, 2001; Deng and Roux, 2004). This problem can be alleviated by using nonlinear scaling of vdW interactions (Simonson, 1993; Simonson, 2001). An efficient way to solve this problem was proposed in the staged protocol developed by Deng and Roux (2004) It is based on the Weeks, Chandler, and Andersen scheme to separate repulsive and attractive parts of the LJ potential (Weeks *et al.*, 1971). Then the linear coupling scheme is used for a slowly varying attractive LJ contribution, whereas the repulsive part is gradually transformed into a soft core potential controlled by a nonlinear staging parameter varying from 0 to 1 (Deng and Roux, 2004). This approach can be efficiently used for solvation and protein-binding free energy calculations (Deng and Roux, 2004; Deng and Roux, 2006).

8.4.2.3 **Energetic Decompositions**

It is often of interest to determine how much a particular subset of atoms in the system, or a particular energetic term, contributes to the free energy. The simplest contributions to be calculated are just energetic contributions. One may compute a contribution from a particular interaction between some groups of atoms, or perhaps a type of interaction (e.g. electrostatic or LJ) as a function of reaction coordinate.

$$\langle U_\alpha(\mathbf{R}, z)\rangle (z) = \frac{\displaystyle\int d^{3N-1}\mathbf{R}\; U_\alpha(\mathbf{R}, z) e^{-U(\mathbf{R},z)/kT}}{\displaystyle\int d^{3N-1}\mathbf{R}\; e^{-U(\mathbf{R},z)/kT}} \quad (36)$$

One may also wish to divide energies up into some meaningful contributions for a given problem. For example, if the reaction coordinate is the position of a solute moving through a system, one may wish to divide the energy into "direct" interactions with the solute and "indirect" interactions that change as the solute passes (e.g. strains on the system). For example,

$$\langle U_I(\mathbf{R})\rangle (z) = \frac{\displaystyle\int d^{3N-1}\mathbf{R}\; U_I(\mathbf{R}) e^{-[U_D(z,\mathbf{R})+U_I(\mathbf{R})]/kT}}{\displaystyle\int d^{3N-1}\mathbf{R}\; e^{-[U_D(z,\mathbf{R})+U_I(\mathbf{R})]/kT}} \quad (37)$$

which shows that all energy terms affect the mean contribution from any one, via the Boltzmann factor in the configurational integral. IEs maybe computed through an IE calculation between two subsets of atoms, possibly with some truncation of nonbonded terms, as explained previously. However, potential energy contributions do not tell the entire story.

One may also calculate entropic contributions to the PMF. The usual practice for extracting the entropy is to analyze temperature variations in free energy

$$S = -\frac{dG}{dT} \quad (38)$$

but which requires simulations at multiple temperatures (Maccallum and Tieleman, 2003), followed by FD calculation. A simple alternative is to estimate the entropic contributions at a single temperature via

$$-T\Delta S = \Delta G - \Delta H \quad (39)$$

where the enthalpic contribution includes the average internal energy of the system as well as the pressure–volume work. This approach is simple but does suffer the limitation that large fluctuations in the energy are transferred to the resulting entropic estimate.

In many instances, entropic contributions can be as significant as enthalpic contributions to a free energy change. One would really prefer to have a means of decomposing the free energy into contributions from particular interactions or energetic terms. The relationship between the PMF and the mean force (Eq. (28)) permits a decomposition from different interactions, α

$$W_\alpha(z) = W_\alpha(z') - \int_{z'}^{z} d\zeta \langle F_\alpha(\zeta)\rangle \quad (40)$$

where F_α is the instantaneous force of that component. This mean force decomposition is meaningful because forces acting on the protein are additive and related to free energy by simple integration.

8.4.2.4 Multidimensional PMFs

Often a process is governed by more than one coordinate, The objective then is to compute the function, $W(z, s)$ as a function of a secondary coordinate, s, also.

$$W(z, s) = -kT \ln\langle \rho(z, s)\rangle \tag{41}$$

A similar expression could be written for more than two coordinates to create a multidimensional free energy surface. In principle, the distribution of many coordinates could be obtained from unbiased simulation. However, when the time to equilibrate one or more of those degrees of freedom exceeds manageable simulation times one may wish to bias the sampling of more than one coordinate.

In the case where one coordinate has already been biased, calculation of the 2D free energy surface is simple. Once the WHAM equations (Eqs. (31) and (32)) have been iterated to convergence for the 1D PMF calculation, any distribution $\langle \rho(z, s)\rangle_{(i)}^{\text{bias}}$, biased by window function $w_i(z)$ acting on the z coordinate, but involving some secondary variable s, may be unbiased via an extension of the 1D WHAM equations (Allen *et al.*, 2006a),

$$\langle \rho(z, s)\rangle = \frac{\displaystyle\sum_{i=1}^{N} n_i \langle \rho(z, s)\rangle_{(i)}^{\text{bias}}}{\displaystyle\sum_{i=1}^{N} n_i e^{-[w_i(z)-F_i]/kT}} \tag{42}$$

where n_i is the number of time steps in window i, and F_i are the free energy constants obtained from solution to the 1D WHAM equations. However, this unbiasing procedure can be avoided. Defining the function $\rho(s|z)$ by

$$\langle \rho(z, s)\rangle_{(i)}^{\text{bias}} = \langle \rho(z)\rangle_{(i)}^{\text{bias}} \cdot \rho(s|z) \tag{43}$$

where the conditional probability $\rho(s|z)$ (probability of having a value of s, given a value of z) is normalized, then the unbiased distributions, related to the biased distributions via Eq. (42), possess a similar relation

$$\langle \rho(z, s)\rangle = \langle \rho(z)\rangle \cdot \rho(s|z) \tag{44}$$

The 2D PMF, $W(z, s)$, is then simply obtained from $W(z)$ by

$$\begin{aligned} W(z, s) &= -kT \ln \langle \rho(z, s)\rangle \\ &= W(z) - kT \ln \langle \rho(s|z)\rangle + C \end{aligned} \tag{45}$$

where C is some additive constant. However, if the second variable also requires biasing then a full 2D WHAM analysis of 2D umbrella sampling windows is required (Souaille and Roux, 2001).

Having obtained a multidimensional free energy surface it is often interesting to extract the free energy along any one coordinate; where the other coordinates are sampled in their equilibrium distributions. To do this, one may integrate over the secondary variable, s, to reveal the 1D PMF, $W(z)$,

$$e^{-W(z)/kT} = C \int ds\, e^{-W(z,s)/kT} \tag{46}$$

In some cases, the definition of the 1D PMF from a 2D PMF can be problematic, if the secondary coordinate becomes unbound for any range of z. Such a situation emerges from analysis of ion permeation through ion channels, for example, where an ion leaving the channel becomes unbounded and experiences an infinite entropic increase (Roux *et al.,* 2008). In such cases of binding free energy profiles one must place a limitation on the bounds of the secondary coordinate that maybe easily sampled during a simulation (i.e. the lateral displacements of the ion exiting the ion channel). This constraint must then be rigorously unbiased. Because the configurational integral of Eq. (46) is not defined as the ion becomes unbounded (outside the channel) we can restrict lateral displacements with a flat-bottom cylindrical constraint of radius R. We can represent this by a Heaviside step function $H(x, y)$ which is 1 inside the bounding cylinder and 0 outside, such that (Allen *et al.,* 2006a)

$$e^{-W(z)/k_\mathrm{B}T} = C \int dx\, dy\, H(x, y)\, e^{-W(x,y,z)/kT} \tag{47}$$

where C is some constant. By setting $W(z') = 0$ at the position $z = z'$ far from the protein, C becomes

$$C = \frac{1}{\displaystyle\int dx\, dy\, H(x, y)\, e^{-W(x,y,z')/kT}} \tag{48}$$

If W is independent of x and y at $z = z'$, then $W(x, y, z') = W(0, 0, z')$ and

$$C = \frac{e^{+W(0,0,z')/kT}}{\pi R^2} \tag{49}$$

such that (Allen *et al.,* 2004b)

$$e^{-W(z)/k_\mathrm{B}T} = \frac{1}{\pi R^2} \int dx\, dy\, H(x, y) \times e^{-[W(x,y,z)-W(0,0,z')]/kT} \tag{50}$$

The multidimensional PMF can also be used for extracting average properties $\mathcal{X}(z, s)$ or $\mathcal{X}(z)$ through similar projections to the PMF. A 2D histogram of a property can be formed on the same grid as the 2D PMF, $\langle \mathcal{X}(z, s) \rangle$, and then the second coordinate can be integrated over

$$\langle \mathcal{X}(z) \rangle = \frac{\displaystyle\int ds\, \langle \mathcal{X}(z, s) \rangle\, e^{-W(z,s)/kT}}{\displaystyle\int ds\, e^{-W(z,s)/kT}} \tag{51}$$

Similarly one may analyze mean force decompositions in this way (Dorairaj and Allen, 2007). Other manipulations of multidimensional PMFs can also be carried out, such as the remapping of free energy to obtain a PMF along any linear combination of PMF coordinates (see (Li *et al.,* 2008a) for an illustration).

8.4.2.5 **Computing Equilibrium Constants: The Case of pK_a Calculation**

The typical approach for pK_a computation is to simulate the deprotonation process via FEP. If one wishes to compute the pK_a of some residue, R, at a position, $\mathbf{r}$, in space, then one must compute the free energy change for the process

$$\mathrm{RH}^+(\mathbf{r}) \rightarrow \mathrm{R}^0(\mathbf{r}) + \mathrm{H}^+(\mathrm{aq}) \tag{52}$$

This free energy is equal to

$$\Delta G_\mathrm{deprot}(\mathbf{r}) = (G_{R^0}(\mathbf{r}) + G_{H^+}) - G_{\mathrm{RH}^+}(\mathbf{r}) \tag{53}$$

as well as at a position in the bulk $\mathbf{r}'$

$$\Delta G_\mathrm{deprot}(\mathbf{r}') = \left(G_{R^0}(\mathbf{r}') + G_{H^+}\right) - G_{\mathrm{RH}^+}(\mathbf{r}') \tag{54}$$

The difference between these two free energies leads to a cancellation of the free energy of the unconstrained aqueous proton G_{H^+} and is

$$\begin{aligned}\Delta\Delta G_{\text{deprot}} &= \left(G_{R^0}(\mathbf{r}) - G_{R^0}(\mathbf{r}')\right) \\ &\quad - \left(G_{\text{RH}^+}(\mathbf{r}) - G_{\text{RH}^+}(\mathbf{r}')\right) \\ &= (G_{R^0}(\mathbf{r}) - G_{\text{RH}^+}(\mathbf{r})) \\ &\quad - \left(G_{R^0}(\mathbf{r}') - G_{\text{RH}^+}(\mathbf{r}')\right) \\ &= \Delta G_{\text{deprot}}(\mathbf{r}) - \Delta G_{\text{deprot}}(\mathbf{r}') \end{aligned} \tag{55}$$

Thus, the deprotonation process corresponds simply to a mutational transformation from protonated RH^+ to neutral R at two positions. The free energy difference, ΔG, can be computed via thermodynamic perturbation. As we shall show later in this chapter, convergence of this procedure can be difficult to achieve if the protonation event involves significant conformational change of the protein or surrounding membrane or solvent. An alternative approach is to employ a thermodynamic cycle where $\Delta\Delta G_{\text{deprot}}$ can be seen to equal the difference between the PMFs for charged and neutral R from a reference position, z' to a position, z along the chosen reaction coordinate:

$$\Delta\Delta G_{\text{deprot}} = W_{R^0}(z) - W_{\text{RH}^+}(z) \tag{56}$$

(where the PMF has already been defined relative to the reference position, z', via Eq. (30)). Then the change in free energy of deprotonation is related to the pK_a shift via

$$\Delta \text{p}K_a = \Delta\Delta G_{\text{deprot}}/2.3\ kT \tag{57}$$

8.4.2.6 Computing Equilibrium Constants: An Example of Binding Constants

A single-particle dissociation constant K_D can be expressed in terms of the three-dimensional PMF, $W(\mathbf{r})$ (Roux, 1999)

$$K_D^{-1} = \frac{\int d\mathbf{r}\, \mathcal{H}_{\text{site}}(\mathbf{r})\, e^{-W(\mathbf{r})/kT}}{e^{-W(\mathbf{r}')/kT}} \tag{58}$$

where the binding site is defined by a Heaviside step function $\mathcal{H}_{\text{site}}(\mathbf{r})$ which is 1 inside the binding site and 0 outside. K_D may also be expressed in terms of the 1D PMF, $W(z)$ (Allen *et al.*, 2004b). We define the binding site to be within the range $z_{\min} \le z \le z_{\max}$

$$\mathcal{H}_{\text{site}}(\mathbf{r}) = h_{\text{site}}(z)\, H(x, y) \tag{59}$$

where

$$h_{\text{site}}(z) = \begin{cases} 1; & z_{\min} \le z \le z_{\max} \\ 0; & z < z_{\min} \\ 0; & z > z_{\max} \end{cases} \tag{60}$$

then, with $\mathbf{r}' = (0, 0, z')$, Eq. (58) becomes

$$\begin{aligned} K_D^{-1} &= \int dx\, dy\, dz\, \mathcal{H}_{\text{site}}(x, y, z) \\ &\quad \times e^{-[W(x,y,z) - W(0,0,z')]/kT} \\ &= \int dz\, h_{\text{site}}(z) \int dx\, dy\, H(x, y) \\ &\quad \times e^{-[W(x,y,z) - W(0,0,z')]/kT} \end{aligned} \tag{61}$$

Then, using Eq. (50), we find the relationship between the dissociation constant and the 1D PMF

$$\begin{aligned} K_D^{-1} &= \pi R^2 \int dz\, h_{\text{site}}(z) e^{-W(z)/k_B T} \\ &= \pi R^2 \int_{z_{\min}}^{z_{\max}} dz\, e^{-W(z)/k_B T} \end{aligned} \tag{62}$$

where R is the radius of the bounding cylinder used to restrain lateral/secondary coordinates (Allen *et al.*, 2004b).

8.4.2.7 Computing Flux along a Free Energy Path

Having mapped out the free energy surface for a process, one maybe interested in estimating the stationary flux along a given path. Such a calculation involves estimation of the spatially varying diffusion constant and applying a rate model. For instance, the Kramer's transition rate can be computed in the high friction, large activation regime (Allen *et al.*, 2003b; Crouzy *et al.*, 1994)

$$k_{tr} = \frac{D(z_{\text{barrier}})}{2\pi kT} \times \left[-W''(z_{\text{barrier}})W''(z_{\text{well}})\right]^{1/2} \times e^{-\Delta W_{\text{activation}}/kT} \qquad (63)$$

where $D(z_{\text{barrier}})$ is the diffusion constant measured near the top of the barrier in the z-direction, $W''(z)$ the second derivative of the PMF at the barrier and wells, and $\Delta W_{\text{activation}}$ is the activation barrier height for the transition. The stationary flux (J) across a 1D free energy profile can be determined from a 1D Nernst–Planck equation (Levitt, 1986)

$$J = -D(z)\frac{dP(z)}{dz} - P(z)\frac{D(z)}{kT}\frac{dW_{\text{total}}(z)}{dz} \qquad (64)$$

where $D(z)$ is the diffusion coefficient on that reaction coordinate and $P(z)$ is the spatial probability density. The PMF has been substituted for a "total" PMF in this expression to allow for the application of a nonequilibrium driving potential, such as an electrical membrane potential that would drive ions across ion channels in a cell membrane (Allen *et al.*, 2004b). In that case, W_{total} can be expressed as a sum of the equilibrium PMF W, and the interaction of atomic charges, q_i (at positions z_i), with the scalar potential arising from the asymmetrical charge distribution across the membrane, ϕ.

$$W_{\text{total}}(z) = W(z) - kT\ln\left\langle e^{-\sum_i q_i\phi(z_i)/kT}\right\rangle \qquad (65)$$

where z is the location of the ion and the brackets represent an equilibrium average. Different levels of approximation to Eq. (65) can be made, as discussed in (Allen *et al.*, 2006b). In particular, the charge distribution of the protein and its hydration waters can be represented by the moments of its dipole distribution and a cumulant expansion of the above expression obtained. However, at physiological voltages the impact of the voltage on the PMF is dominated by the movement of the ion where, to a first approximation, one can assume that the system charge distribution is independent of ion position and therefore that (Allen *et al.*, 2006a)

$$W_{\text{tot}}(z) \approx W(z) + q_{\text{ion}}\phi_{\text{mp}}(z) \qquad (66)$$

In the limit of zero applied voltage simple expressions for the stationary flux that have been obtained (Allen *et al.*, 2006a) will be solved later in this chapter.

8.4.3
Advanced Sampling and Nonequilibrium Approaches

PMF computation is complicated by the wide-ranging length and timescales of the thermal fluctuations in the biological system (Cooper *et al.*, 1985; Allen *et al.*, 2004a). The timescales of protein conformational changes and membrane dynamics add a further challenge. Improvements in sampling can be obtained through the Umbrella Sampling technique by using more sophisticated biasing potentials. In particular, adaptive biasing approaches (Darve and Pohorille, 2001; Darve *et al.*, 2002; Henin and Chipot, 2004; Rodriguez-Gomez *et al.*, 2004; Chipot and Henin, 2005) allow the simulation to "learn" from previous trajectory to better bias the coordinate and obtain a more uniform distribution. However, in some instances the very choice of order parameters for a PMF calculation becomes complicated, as several coordinates may equilibrate on very long timescales.

The Replica Exchange Method (Swendsen and Wang, 1986; Sugita and Okamoto, 1999) (REM), expedites configurational sampling on a rugged energy surface by introducing random walks by exchanging parallel simulations with different temperatures. This method lends itself to ordinary computer clusters because the replicas are run, for the most part, independently on separate CPUs (Fukunishi *et al.*, 2002). However, as the number of degrees of freedom, f, increases, the distribution of energies in each system becomes very narrow, reducing the transition probabilities between neighboring replicas. As a result, the number of systems required for sufficient exchanges grows as $O(f^{1/2})$. This seems an unnecessary burden when most of the degrees of freedom are associated with solvent. A proposed remedy for this is Hamiltonian REM, where instead of changing temperature between replicas (i.e. effectively scaling the entire Hamiltonian), just part of the Hamiltonian, associated with slow varying coordinates, is scaled leading to severalfold increase in efficiency (Fukunishi *et al.*, 2002). Replicas with weaker interactions will have a smoother energy surface and better configurational sampling. Replicas are mixed via Monte Carlo (MC) exchanges during the simulation using a Metropolis (Metropolis *et al.*, 1953) transition probability

$$W(X, U_m; Y, U_n) = \begin{cases} 1; & \Delta \leq 0 \\ e^{-\Delta} & \Delta > 0 \end{cases} \tag{67}$$

where replica m is in configuration X, with Hamiltonian $U_m(X)$, and replica n is in configuration Y, with Hamiltonian $U_n(Y)$, and

$$\Delta = [(U_m(Y) + U_n(X)) - (U_m(X) + U_n(Y))]/kT \tag{68}$$

Taking this method a step further, Hamiltonian REM could be combined with umbrella sampling (by exchanging Hamiltonians and window functions) to obtain enhanced sampling and PMFs as a function of desired coordinates (Sugita *et al.*, 2000).

A completely different approach to these methods is to use nonequilibrium sampling. By simulating with an applied force one can explore rare configurations in relatively short times and this has been used successfully to study processes such as ion permeation (Isralewitz *et al.*, 2001a; Gullingsrud and Schulten, 2003; Liu *et al.*, 2006; Zhang *et al.*, 2006; Bastug *et al.*, 2008), protein–ligand binding/unbinding (Isralewitz *et al.*, 1997; Isralewitz *et al.*, 2001b), protein translocation (Monticelli *et al.*, 2005) and protein unfolding (Krammer *et al.*, 1999; Paci and Karplus, 2000; Isralewitz *et al.*, 2001b; Gao *et al.*, 2003), for example. In steered molecular dynamics (SMD) simulations the time-dependent force is applied to pull the system along some particular degrees of freedom (Isralewitz *et al.*, 2001b). In the constant velocity pulling method an atom being pulled is attached via a harmonic spring to some restraint point (dummy atom) moving with certain velocity (Lu *et al.*, 1998). In another method the restraint point does not move but the spring stiffness increases over time (Isralewitz *et al.*, 2001a). SMD methodology is closely related to experimental techniques such as atomic force microscopy or optical tweezers (Isralewitz *et al.*, 2001b). The direction of the applied force plays an important role in SMD simulations and can be chosen to be random, guessed from structural information or obtained from the so-called targeted MD, which employs time-dependent holonomic constraints to move from one state of the system (e.g. protein conformation) to another (Schlitter *et al.*, 1993). The direction of movement from initial to final state can be then used in SMD (Isralewitz *et al.*, 2001a). The magnitude and pathway of the pulling can be also controlled manually using haptic device in a technique called interactive molecular dynamics (IMD) (Grayson *et al.*, 2003).

But such nonequilibrium approaches can also be used to learn about equilibrium properties of the system using the Jarzynski equality (JE) (Jarzynski, 1997)

$$\Delta G = -kT \ln\left\langle e^{-\tilde{W}/kT}\right\rangle \tag{69}$$

where $\tilde{W}$ is work done on the system. The JE was derived first on the basis of Hamiltonian equations of motions but generalized later by Crooks (1998, 2000) for other systems, for which dynamics is Markovian and microscopically reversible. JE demonstrates that the work required to follow each of an ensemble of nonequilibrium paths, $\tilde{W}(z)$, can be used to calculate the equilibrium PMF. This methodology combined with SMD thus can serve as a viable alternative to umbrella sampling techniques (Park and Schulten, 2004; Kosztin *et al.*, 2006). Moreover, SMD might be considered equivalent to umbrella sampling MD simulations in the limit of weak slowly changing in time external forces inducing only minor changes (Isralewitz *et al.*, 2001b).

JE has been used in both simulations using SMD or similar methods (Xiong *et al.*, 2006; Bastug and Kuyucak, 2007; Bastug *et al.*, 2008) as well as experiments (Hummer and Szabo, 2001); (Liphardt *et al.*, 2002). The application of very large forces not only allows one to sample very rare events in short simulations, but also can be unbiased accordingly (Wereszczynski and Andricioaei, 2006). This formalism can also be applied to calculation of other thermodynamic properties, for example entropic and enthalpic contributions without the necessity to run simulations at several temperatures (Nummela *et al.*, 2008). The major concern with JE-based simulation methodology is sampling, especially for large biomolecular systems (Frenkel and Smit, 2002; Xiong *et al.*, 2006).

A wide array of improved sampling methods, both equilibrium and nonequilibrium, have been developed in recent years (see Adcock and McCammon (2006) for a recent review), yet in this chapter we focus on standard techniques as illustrations.

8.5
Case Studies

8.5.1
Ion Channel Permeation

We consider an important class of membrane-proteins, known as *ion channels,* which allow selective permeation of charged molecules across the cell membrane. Ion channels are excellent probes for the state of the bilayer because they have a direct measure of function (electrical current) and benefit from decades of structural and functional studies. We consider the gA channel (Urry, 1971) as a prototypical example because of its simplicity and extensive experimental characterization. The gA channel forms by TM dimerization of single stranded, right-handed β-helical monomers (Urry, 1971). With known structure (Arseniev *et al.*, 1986; Townsley *et al.*, 2001; Ketchem *et al.*, 1997; Allen *et al.*, 2003b) and extensive functional studies (Hladky *et al.*, 1979; Eisenman and Horn, 1983; Andersen and Koeppe, 1992; Busath, 1993; Andersen *et al.*, 2005), gA is an ideal prototype for studies of ion permeation and selectivity in narrow pores. The dimer is shorter than typical lipid bilayers and can lead to a ‘‘hydrophobic mismatch’’ and corresponding free energy cost for the membrane to accommodate the channel (Lundbaek *et al.*, 1997). As a result, gA activity is sensitive to the composition of the surrounding membrane and has become a useful ‘‘probe’’ for membrane structure and composition. The gA channel poses a significant challenge for computational investigation because of the need to accurately represent both the interactions between ions and bulk water and ions and the protein in an almost dehydrated state.

For the sake of simplicity, ion channel proteins have often been pictured as rigid macromolecules, immersed in an implicit solvent continuum. Many permeation models have used a single rigid structure and continuum methods to represent interactions inside narrow ion channels, yet ion energetics can be very sensitive to the precise location of protein atoms and their ability to undergo a flexible response (Allen *et al.*, 2004a). It has long been known that proteins have a rather fluid-like nature (Cooper, 1976) that undergo thermal fluctuations, from subpicosecond vibrations, to multinanosecond global reorientations and side chain isomerizations and eventually μs to second conformational changes (Karplus and McCammon, 1981). In particular, with single permeation events requiring 10–100 ns, extensive protein and solvent fluctuations occur during ion translocation through a pore. The effects of fluctuations on protein function has been known for several decades (Northrup *et al.*, 1982; Perutz and Mathews, 1966; Takano, 1977) and numerous simulations have suggested significant atomic fluctuations in ion channels such as gA (Mackay *et al.*, 1984; Roux and Karplus, 1991) and the KcsA potassium channel (Allen *et al.*, 1999; Guidoni *et al.*, 1999; Allen *et al.*, 2000; Aqvist and Luzhkov, 2000; Berneche and Roux, 2000; Shrivastava and Sansom, 2000; Noskov *et al.*, 2004). Experimental results on thermal fluctuations in proteins (Frauenfelder *et al.*, 1979; Parak and Knapp, 1984; Ringe and Petsko, 1986; Gabel *et al.*, 2002), the ion-induced reorganization of the KcsA pore (Zhou *et al.*, 2001) as well as simulation-based calculations all show that proteins are flexible on subangstrom length scales, with significant response to perturbative forces, such as those arising from ions, which cannot be neglected in narrow ion channels (Allen *et al.*, 2004a). In addition to thermal fluctuations, discrete water molecules gives rise to structural effects on length scales under 10 Å (Israelachvili and Wennerström, 1996). It is therefore essential to study ion permeation using fully atomistic MD simulation.

8.5.1.1 **Simulation Details**

Simulations were carried out with the program CHARMM (Brooks *et al.*, 1983) using the PARAM27 (MacKerell, 1998b; Schlenkrich *et al.*, 1996) protein/lipid force field with TIP3P water (Jorgensen *et al.*, 1983) parameters and ion LJ parameters from Beglov and Roux (1994). Dimyristoylphosphatidylcholine (DMPC) bilayers of different sizes were built around the gA protein using extensions of existing membrane-building techniques (Woolf and Roux, 1996) (Figure 8.1a). The gA helical dimer (PDB:1JNO) (Townsley *et al.*, 2001), has been shown to provide agreement with a range of experimental solution and solid-state nuclear magnetic resonance observations (Allen *et al.*, 2003b) and was used for these studies. Membranes consisted of ~1 or 3 shells of phospholipids, containing 20 or 96 lipid molecules (and 1080 or 3996 water molecules), respectively (though for illustration we shall show results only for the smaller system here). Hexagonal periodic boundaries were chosen, because they provide more efficient use of lipid patch, with respective xy-translation lengths 32.1 and 61.9 Å. Pressure coupling was employed in the z direction (parallel to the membrane normal, with average height ~75 Å), while the x–y dimensions of the box remained fixed to ensure correct lipid structure for this CHARMM force field. Ionic solutions of 1 M KCl were used to ensure good electrolyte sampling. Particle-mesh Ewald, SHAKE on bonds involving H atoms and Nose–Hoover constant pressure and temperature algorithms were employed. The temperature of 330 K ensured the system remained well above the gel-phase transition temperature for the lipid bilayer and enhanced configurational sampling.

8.5.1.2 **Free Energy Profile Calculation**

At moderate concentrations the gA pore is singly occupied such that a one-ion PMF, $W(\mathbf{r})$, can be used to model the flux of ions through the pore. We choose a reference $W(\mathbf{r}') = 0$ at a position $\mathbf{r}\prime = 30$ Å in the bulk where the free energy surface has become flat. The one-ion pore region has been determined to be defined approximately by a sphere of radius 14 Å (Allen *et al.*, 2006a) around the COM of the gA dimer. This is the largest sphere for which two cations on one side of the channel is not seen, and for which anions are not observed. However, it is possible to have one cation on each side of the channel (Allen *et al.*, 2006a) and thus a spherical repulsive flat-bottom spherical harmonic restraint with force constant 5 kcal mol^{-1} was used to maintain a one-ion PMF.

Because conduction is driven by a transmembrane voltage difference we choose a reaction coordinate z, parallel to the fixed membrane normal, that is the distance of the ion to the COM of the gA dimer. Because the configurational integral of Eq. (30) will not be defined as the ion leaves the channel and becomes unbounded, we restrict lateral displacements with a flat-bottom

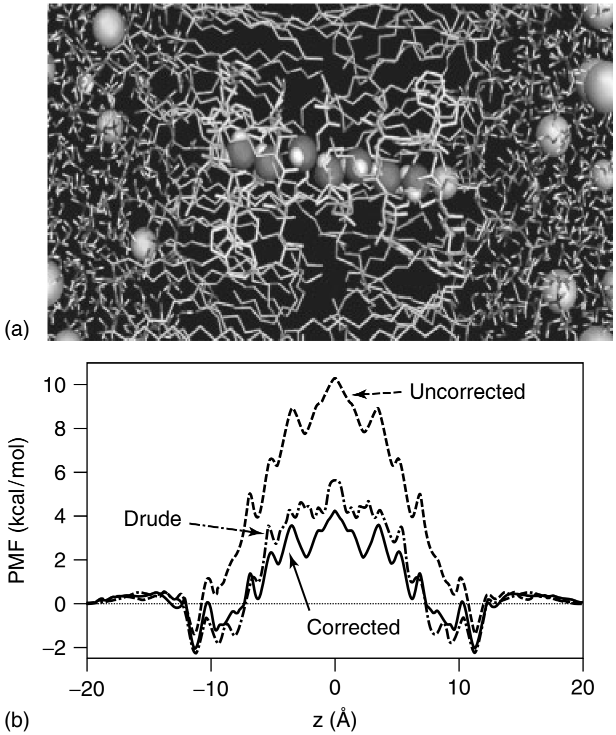

Fig. 8.1 Gramicidin A ion channel. (a) gA protein (yellow) embedded in a hydrated DMPC membrane (gray hydrocarbon tails, water molecules as red and white sticks, potassium ions as green balls and chloride ions as gray balls) with membrane normal oriented horizontally. Water molecules inside the narrow pore are shown as balls. (b) 1D PMF for permeation before any artifact corrections ("uncorrected", dashed), after postsimulation corrections ("corrected", solid) and after simulation with a Drude-polarizable membrane hydrocarbon core ("Drude", dash-dot) (adapted from (Allen *et al.*, 2004b) with "Drude" curve added). (Please find a color version of this figure on the color plates.)

cylindrical constraint of radius $R = 8$ Å and force constant 10 kcal mol^{-1} Å^{-2} (Allen *et al.*, 2004b). This radius is large enough such that it is not felt for an ion inside the channel but small enough such that it maybe thoroughly sampled in a short simulation. The use of alternative constraints on lateral displacements can cause poorly defined artifacts in PMF calculations (Roux *et al.*, 2008). We calculated this PMF with umbrella sampling using 101 simulations, biased by harmonic window functions with force constant 10 kcal mol^{-1} Å^{-2} that hold the ion at 0.5 Å increments in $z = (-20, +30)$ Å.

To obtain starting configurations it is important not to generate too large a perturbation owing to the sudden placement or pulling of an ion that may take the system too far from equilibrium. We avoid any "dragging" procedure that would pull ions into the narrow pore so as to maintain a correct protein and vicinal water geometry. We instead place ions at regular positions by replacing either existing ions, or if ions do not exist closeby, at water positions and then displace that water molecule. This procedure involves searching every frame of a 4 ns unbiased MD trajectory for the best possible starting configuration (Allen *et al.*, 2006a). Simulation times of 2 ns/window are needed in order to obtain reliable simulations, as shown in the analysis of Allen *et al.* (2006a). Shorter simulations can lead to asymmetries in the 1D PMF of several kilocalories per mole. One should simulate long enough that asymmetries drop to a desired level (1 kcal mol^{-1} or less, perhaps) and then may impose symmetry on the PMF. Such levels of asymmetry correspond to very small average force across the channel (orders of magnitude smaller than the average magnitude of the instantaneous force). Symmetrization should not be imposed after solving the WHAM equations but before, as this can assist in the solution of the iterative equations.

Figure 8.1b shows the symmetrized 1D PMF after 2 ns of simulation per window (dashed curve), over a reduced range $-20 \leq z \leq 20$, with average error of $\sim$0.3 kcal mol^{-1} (Allen *et al.*, 2006a). The PMF exhibits a central barrier of $\sim$11 kcal mol^{-1} with respect to the binding site. We refrain from calculating a barrier with respect to the unbound bulk reference because this is dependent on the choice of lateral constraining method. There is a deep outer binding site at $z = 11.3$ Å, and a less deep inner binding site at 9.7 Å. The positions of these minima are consistent with experiments, with the 2D PMF surfaces, to be described below, shedding more light on this agreement.

The magnitude of the barrier in Figure 8.1b has been shown to be too great for agreement with experimental flux measurements (Allen *et al.*, 2004b). However, the system setup suffers from artifacts owing to the finite size of the membrane patch and the inadequate description of the hydrocarbon core of the lipid membrane (Allen *et al.*, 2004b). The finite size of the patch, combined with periodic boundaries, leads to an artificial destabilization of an ion as it enters a lower dielectric membrane environment relative to the high dielectric aqueous phase. Poisson–Boltzmann solutions have shown that the finite size effect can overestimate the barrier by 1.6 kcal mol^{-1}, as confirmed by simulations with larger membrane patches (Allen *et al.*, 2006a). The lacking electronic polarizability of the MD force field for hydrocarbon results in a dielectric constant of $\sim$1 instead of the experimental value of $\sim$2 for hydrocarbon tails of lipids. The effect has been calculated by either Poisson–Boltzmann solutions using a thermodynamic cycle as described previously (Allen *et al.*, 2006a) with a correction of 2.1 kcal mol^{-1} needed. This correction has also been estimated by obtaining average shifts in energy when polarizability of the lipid tails is added *a posteriori*. Drude oscillators (Vorobyov *et al.*, 2005) have been added to all lipid carbon atoms to obtain a result consistent with the Poisson–Bolztmann solutions, but slightly larger corrections up to 3.6 kcal mol^{-1} at the center of the channel (see solid "corrected" curve). The lacking electronic polarizability of the lipid tails may also introduce other artifacts, such as an artificially high dipole potential of the membrane (Klauda *et al.*, 2008). However simulations of the membrane-protein system with the polarizable lipid core included during simulations (dash-dot "Drude" curve) have led to similar results to post-corrections, indicating that the changes in membrane dipole potential are not experienced by the ion inside the ion channel.

8.5.1.3 Connection with Observables

We calculated the flux through the ion channel in the limit of low membrane voltage. This maximum conductance, based on the corrected PMF (solid curve in Figure 8.1b), was found to be 9.3 pS, only a factor of 2 from the experimental value of 21 pS (in similar branched DPhPC (diphytanoylphosphatidylcholine) bilayers with 1 M KCl at 100 mV (Busath *et al.*, 2003)). This indicates that the PMF for K^+ conduction through the gA ion channel is likely within a kilocalories per mole of the true free energy profile.

We calculate the single-ion dissociation constant for the channel of 0.14 M using the same corrected PMF (and 0.07 M with the "Drude" PMF), in agreement with experimental values from NMR and conductance studies: 0.07 M (Andersen *et al.*, 2005) (in DPhPC/*n*-decane bilayers); 0.017 M (Jing *et al.*, 1995) (measured in dodecylphosphocholine micelles); 0.019–0.73 M (Hinton *et al.*, 1986) (in aqueous lysophosphatidylcholine dispersions); and 0.035 M (Thompson *et al.*, 2001) (in glycerylmonoolein bilayers). We have also determined that the ion preferentially binds to the outer binding site ($10.2 < z < 12.5$ Å) with $K_D = 0.83$ M as compared to the inner site ($6.9 < z < 10.2$ Å) with $K_D = 3.6$ M. This is in agreement with Tian and Cross (1999) who observed a larger chemical shift for the Leu12-Trp13 than the Leu10-Trp11 linkage for K^+, but is in contrast to X-ray scattering by Olah *et al.* (1991) who see preferred binding nearer the inner site. We again warn that the 1D PMF above establishes a connection to experimental observations of binding and conductance but cannot establish a connection between the channel and bulk environment in terms of relative free energies due to the inability to define the free energy in the unconstrained aqueous phase.

8.5.1.4 Two-dimensional Free Energy Surfaces Reveal Mechanisms

Figure. 8.2a reveals the 2D PMF as a function of membrane normal, z, and radial, r, coordinates (for a greater range see Allen *et al.*, 2006b). This (uncorrected) 2D PMF reveals the free energies of binding sites and the central barrier relative to bulk. The 2D PMF also shows the extent of lateral ion motion, which, in the frame of the membrane normal, includes the influence of channel tilting (12° on average (Allen *et al.*, 2004b)) on the lateral displacements. The outer binding site at $z = 11.3$ Å is the deepest point in the free energy surface, being -3.2 kcal mol^{-1} relative to the bulk. In the narrowest part of the channel, an ion experiences a barrier of 7.2 kcal mol^{-1} relative to the bulk. This barrier has been confirmed to be accurate to the order of $\sim$1 kcal mol^{-1}, with the chosen force field, with free energy perturbation calculations (Allen *et al.*, 2004b).

Although the membrane normal coordinate is pertinent to ion conduction down a membrane potential gradient, an instantaneous channel-axis frame PMF

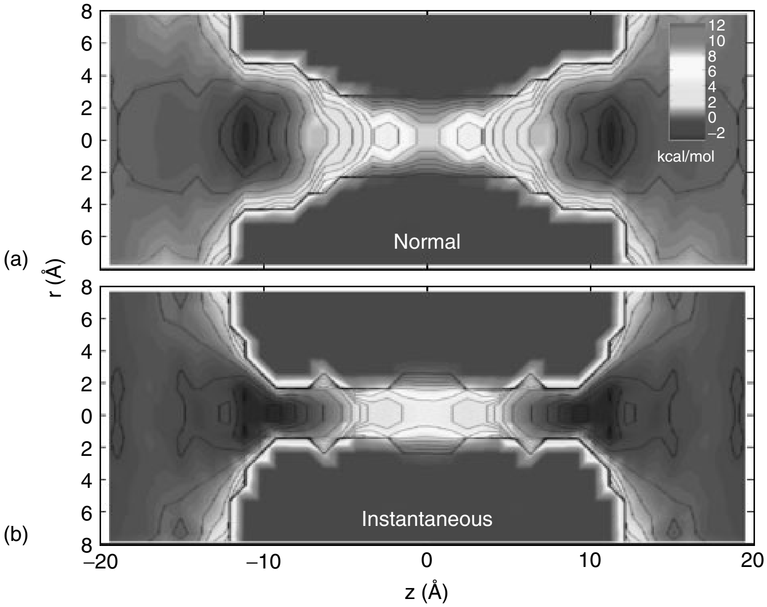

Fig. 8.2 Two-dimensional PMFs for permeation through gA. (a) obtained using a reaction coordinate that is parallel and perpendicular to the membrane normal, (b) obtained using an instantaneously fluctuating channel axis coordinate (adapted from (Allen *et al.*, 2006a)).

should reveal much more about the ion–protein–water interactions (Allen *et al.*, 2006a). We have defined this fluctuating axis coordinate as the position parallel to the vector connecting the centers of mass of the two monomers of gA. Figure 8.2b reveals no wide "free energy vestibules" as seen in Figure 8.2a. It also shows that the outer binding sites are in fact off-axis, as suggested experimentally (Finkelstein and Andersen, 1981), where the ion attains a hydration by three water molecules as opposed to two in the inner site. But what this PMF shows is that the inner binding sites are in fact deeper (by ∼0.5 kcal mol^{-1}) than the outer sites, whereas they were almost nonexistent in the membrane-normal-frame 2D PMF. It was owing to the entropic contribution from being off-axis (occupying a greater volume) that the outer sites were preferred in the original lab-frame PMF. This finding allows one to better reconcile simulation and experiment. In particular, off-axis binding implies greater translational freedom such that the protein backbone will require less distortion to stabilize the ion, and the effect of tilting also must play a role in interpretation of X-ray experiments.

The large stabilization that results from interactions with the single-file pore water (Allen *et al.*, 2004b; Allen *et al.*, 2006a) led us to question whether dehydration could be rate determining. For example, if the ion must wait at a particular position for dehydration to occur then this could suggest that an additional dehydration order parameter may be needed to describe the permeation process (Allen *et al.*, 2004b; Bolhuis *et al.*, 2000). $W(z, n)$ of Figure 8.3a shows the free energy of an ion at z, hydrated by n water molecules in the first shell, relative to $z = 30$ Å where $n \sim 6-7$. Dehydration seems to be a continuous process when entering the narrow pore, dropping to three in the outer site and two in the inner binding site.

However, water in this narrow pore plays a more complicated role. While the water column can be oriented with its dipole running one way or the other in the absence of an ion, ion movement requires an alignment of the water column with oxygen atom adjacent to the cation. Figure 8.3b shows the 2D PMF, $W(z, \mu)$, as a function of the ion position and the dipole moment, μ, of the single-file water molecules. With the ion outside the channel there are two possible dipole moments, ±15 D, evidenced by free energy minima. But when the ion occupies the outer binding site, the preferred state has the water aligned such that the last oxygen atom is coordinating the ion ($\mu = -15$ D). But the ion cannot enter the channel inner site until the column is oriented the correct way. There is a 2–3 kcal mol^{-1} barrier to flip the column while the ion is outside the channel and a smaller barrier of <1 kcal mol^{-1} to flip the

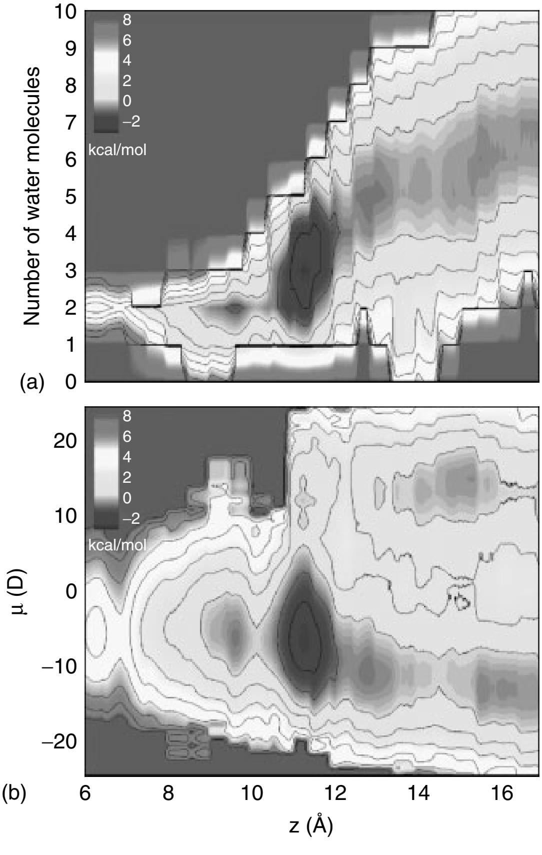

Fig. 8.3 PMFs as a function of position and solvation coordinates. (a) As function of coordination number and (b) as function of dipole moment of the single-file column of water. The restricted range of z ranges from just inside to just outside the narrow pore (adapted from (Allen *et al.*, 2004b)).

single-file column when the ion is in the outer site. Regardless, a sudden change in μ is required for entry with an associated free energy barrier opposing permeation that is not a function of the coordinate z. Any PMF that uses only a single positional order parameter as a reaction coordinate must ensure adequate sampling of slow coordinates such as this water column flipping. Otherwise, two order parameters should be used to describe ion permeation (z and μ) (Allen *et al.*, 2004b).

The dipole moment of the single-file water also complicates conduction calculations at large membrane potentials because it couples to the external potential with nontrivial contributions (Allen *et al.*, 2006a). Moreover, at higher concentrations, multiple ion mechanisms will become more significant. However, the dipole of the single file will contribute to the interaction between multiple ions over the length of the channel. For instance, as an ion approaches from the right in Figure 8.3b, it requires a dipole moment of -15 D to enter. Once it crosses, the chain of waters will have been ''zipped up,'' leaving the dipole moment at $+15$ D, making it difficult for another ion to enter from the right. This suggests a structural long-range coupling across the pore that would be absent in continuum solvent models (Allen *et al.*, 2004b). The mechanism is, however, not so simple because multiple ions will perturb this single-file arrangement.

This case study on gramicidin permeation is by no means complete and has been provided as an illustration of the power of MD simulation when combined with free energy calculation methods. A more complete survey should include permeation studies in other channels, such as potassium, calcium, sodium, and chloride channels. Furthermore, MD simulation has been used not just to study permeation but also to explain how ion channels precisely select between different ion types on the basis of valence (Allen *et al.*, 2006a; Corry *et al.*, 2002), as well as size (Allen *et al.*, 1999; Guidoni *et al.*, 1999; Allen *et al.*, 2000; Luzhkov and Aqvist, 2001; Berneche and Roux, 2001; Noskov *et al.*, 2005; Leung *et al.*, 2006; Bostick and Brooks, 2007). The mechanisms of size selectivity have been an issue of much controversy in recent years. Early explanations of size-based ionic selectivity of potassium channels in terms of the precise geometry of a pore perfectly adapted to snugly fit potassium, but not sodium (Doyle *et al.*, 1998; Yellen, 2002), once one takes into consideration the effects of thermal fluctuations of the protein, are unlikely to be correct (Allen *et al.*, 2004a). While the spatial arrangement of the pore-lining groups is important, it has long been recognized that channels use a combination of geometric, chemical, and energetic factors to select among different ions. Thus while the size of the ion and the channel pore must be similar to allow selective permeation (the so-called sieving mechanism (Mullins, 1960; Hille, 1973)), a complete description of selectivity must include the specific microscopic interactions and their influence on solvation and selectivity (Eisenman, 1961; Eisenman and Horn, 1983; Allen *et al.*, 2004a). More recently, computational models have attempted to elucidate the mechanisms of ion selectivity on the basis of coordination (Bostick and Brooks, 2007; Leung *et al.*, 2006) and specific ion–ligand and ligand–ligand energetics (Noskov *et al.*, 2005) that have brought us much closer to a microscopic understanding of ion channel function.

8.5.2
Models to Explore Voltage-Gated Ion Channel Activation

The second case study considered here is a series of all-atom MD simulations to explore the possibility of the movement of membrane-bound protein segments that contain multiple ionizable amino acid side chains. This study was motivated by recent controversy over the activation mechanisms of voltage-gated ion channel proteins. The voltage-gated potassium channel KvAP contains several Arg side chains in its voltage sensor domains that are designed to sense changes in the membrane voltage and initiate a conformational change in the protein to open up the lumen to allow potassium ion permeation. One proposed model, called the "paddle model," suggests that the Arg-rich S4 segments of the voltage-sensing domains move across the hydrophobic membrane core during activation (Jiang *et al.*, 2003b). Such a motion necessitates the movement of several Arg side chains, known to remain charged, exposed to lipid hydrocarbon. However, theoretically, the cost of moving charges from water across a slab of hydrocarbon is very large and the barrier for this activation has been estimated to be of the order of 200–300 kcal mol^{-1} (Grabe *et al.*, 2004).

Elevating this controversy, small apparent free energies of $\sim$2 kcal mol^{-1} have been measured for moving an Arg side chain along an inserted hydrophobic TM helix (Hessa *et al.*, 2005a). These measurements come from recent cell biological experiments conducted using the translocon/oligosaccharyl transferase machinery of protein synthesis: a very complex process that is currently poorly understood. The nearly zero free energy for membrane insertion of the KvAP S4 peptide alone was also suggested from these studies (Hessa *et al.*, 2005b) as well as recent CG MD simulations (Bond and Sansom, 2007), shown to be inadequate in their ability to reproduce water–membrane partitioning energetics (Vorobyov *et al.*, 2008). Each of these studies has challenged a long-held view that lipid membranes act as barriers for charged and polar species (Parsegian, 1969) and the corresponding theoretical estimates of the associated barriers for a charged Arg to cross a lipid bilayer on the basis of continuum membrane models (Honig and Hubbell, 1984; Kessel and Ben-Tal, 2002; Dorairaj and Allen, 2007; Ulmschneider *et al.*, 2007). However, as pointed out nearly 40 years ago by Parsegian in his pioneering work on membrane permeability, a fundamental limitation of continuum models is the simplified picture of the membrane as a low-dielectric slab segregated from bulk water. In fact, a membrane is fluid-like and will deform under the large electric fields around an ion (Parsegian, 1969). Thus, any model of ion–membrane interactions must allow for this flexible response. We therefore turn to atomistic MD studies that have shown that lipid membranes can undergo substantial deformations in the presence of charged species (Freites *et al.*, 2005; Johansson and Lindahl, 2006; Dorairaj and Allen, 2007; MacCallum *et al.*, 2007; Li *et al.*, 2008a), and elucidate the mechanisms and thermodynamics of such processes using simple model protein systems.

We have obtained spatially resolved free energy profiles of Arg side chain transfer across the lipid bilayer using the all-atom CHARMM force field (MacKerell, 1998b). To test whether low energies seen in translocon experiments

(Hessa *et al.*, 2005) can result from Arg deprotonation, we performed these simulations for both charged and neutral Arg side chain models (Dorairaj and Allen, 2007; Li *et al.*, 2008a), despite the large aqueous pK_a of Arg (12–13.7) (Nozaki and Tanford, 1967; Angyal and Warburton, 1951; Hall and Sprinkle, 1932). We have used simple side chain analog models, methyl guanidinium (MguanH$^+$) and methyl guanidine (Mguan^0), but will not describe those models here. Instead, we focus on simple TM helix models consisting of a charged (ArgH$^+$) or neutral (Arg^0) side chains in the middle of a long 80-residue polyleucine TM helix (Dorairaj and Allen, 2007; Li *et al.*, 2008b; Li *et al.*, 2008a). Other similar studies have been performed recently using different analog models and force fields (MacCallum *et al.*, 2007; MacCallum *et al.*, 2008; Yoo and Cui, 2008; Johansson and Lindahl, 2008).

8.5.2.1 **Simulation Details**

The simulation details of our calculations are provided in the corresponding papers (Dorairaj and Allen, 2007; Li *et al.*, 2008a; Vorobyov *et al.*, 2008) and will be only briefly mentioned here. All simulations were performed using program CHARMM with standard protein (MacKerell, 1998b) lipid (Feller and MacKerell, 2000; Yin and Mackerell, 1998), ion (Beglov and Roux, 1994), and recently developed neutral Arg side chain (Li *et al.*, 2008b) parameters as well as TIP3P water model (Jorgensen *et al.*, 1983). The TM peptide was built initially in the ideal α-helical conformation. The peptide was then placed at the position of interest with the new hydrated membrane built around it asdescribed previously (Woolf and Roux, 1996; Dorairaj and Allen, 2007; Li *et al.*, 2008a). Membrane patches consisted of $\sim$ 2 layers or 48 DPPC lipid molecules. The systems were then solvated with $\sim$ 0.5 M aqueous solution of KCl to provide good sampling of ionic bath and neutralize the positive charge of protonated Arg side chain. Hexagonal PBC with an xy-translation length of $\sim$ 44 Å and an average height of $\sim$ 190 Å were used. The lateral dimensions were based on the experimental area per lipid of 64 Å^2 (Nagle, 1993) and estimated protein cross-sectional area of $\sim$ 180 Å^2, whereas the height was chosen to avoid the TM helix passage through periodic boundaries and minimize its interactions with image peptides.

MD simulations were performed under constant temperature of 330 K (above the gel-phase transition for a pure DPPC bilayer) using a Nose–Hoover thermostat and constant normal pressure of 1 atm while keeping fixed lateral box dimensions using the Langevin piston method. Free energy profiles of Arg side chain translocation across the lipid bilayer were calculated with umbrella sampling using biasing potentials that hold the z component of the peptide COM relative to that of the lipid bilayer. Force constants of 2.5 kcal mol^{-1} Å^{-2} were used, corresponding to RMSF of 0.5 Å and providing good overlap of umbrella sampling windows (Li *et al.*, 2008a). These simulations ran for 5–10 ns after initial equilibration periods to converge solvation IEs. Electrostatic interactions were calculated using PME with a coupling parameter of 0.34 and sixth-order spline for mesh interpolation. Nonbond pair lists were maintained out to 16 Å, whereas vdW as well as real-space electrostatic energies and forces were computed up to 10 Å, with the LJ term truncated via an atom-based shift algorithm (Li *et al.*, 2008a).

8.5.2.2 **Mechanism of Arg Translocation**

Fully atomistic MD simulations have shown that the charged Arg side chain movement across the lipid bilayer is a not a simple dehydration as envisioned by continuum membrane models. When ArgH^+ moves into the membrane core, it disrupts the uniform planar geometry of the bilayer and remains coordinated by ≥ 5 water and ≥ 1 lipid phosphate moieties at all positions across the membrane (see the left-hand inset in Figure 8.4 for an example), as revealed by RDF analysis (Li *et al.*, 2008a). These membrane deformations are due to strong interactions between charged Arg side chain and lipid head groups and water molecules, which are as large as -150 and $-50\,\text{kcal mol}^{-1}$, respectively, and impose significant forces on the bilayer (Dorairaj and Allen, 2007; Li *et al.*, 2008a; Vorobyov *et al.*, 2008). This also can be viewed as the formation of an interfacial connection, which effectively results in local membrane thinning. Furthermore, the Arg side chain can "snorkel" toward a membrane interface, complicating sampling. The proper sampling of interfacial connections and side chain rotamers is necessary to get accurate free energy profiles because connections to both the closest and distant membrane interface must be sampled. This is challenging, however, due to large forces acting on the Arg side chain in the membrane core (up to $10\,\text{kcal mol}^{-1}\,\text{Å}^{-1}$). Once the interfacial connection is established, it does not break during multinanosecond MD simulations (and likely taking hundreds of nanoseconds (Dorairaj and

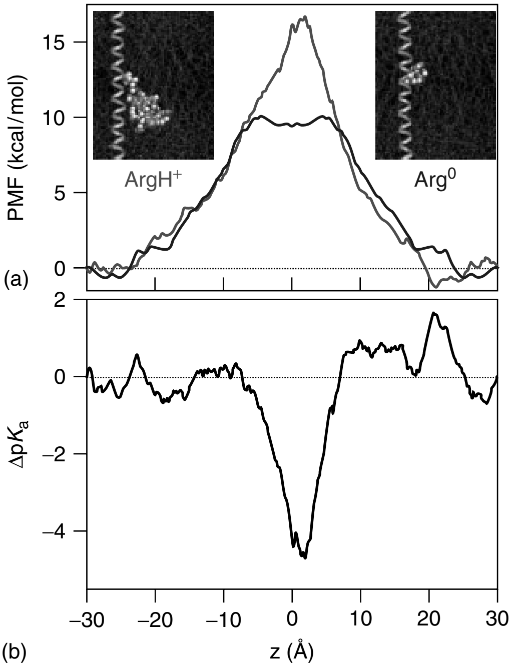

Fig. 8.4 Arginine side chain attached to a TM helix. (a) PMF across the membrane (adapted from (Li *et al.*, 2008a)). MD systems for the charged (ArgH^+) and neutral Arg side chain (Arg^0) with the side chain held near the center of the bilayer are shown as insets revealing membrane deformations in the charged case. Arg is drawn as blue/gray balls, the TM helix as a green ribbon and the hydrated DPPC bilayer with gray C atoms, orange P atoms and red/white water molecules. Lipid phosphate and water atoms that have been pulled into the bilayer core are drawn as balls. The PMFs for charged (red) and neutral (blue) Arg from umbrella sampling simulations are shown. (b) Arg $\text{p}K_\text{a}$ shift profile across the membrane calculated from free energy profiles. (Please find a color version of this figure on the color plates.)

Allen, 2007)). In the innermost ~10 Å the guanidinium group may contact either interface as a result of snorkeling yet in single window simulations will only contact one interface, leading to large artificial average forces and an erroneous PMF calculation. To overcome this challenge, 2D umbrella sampling simulations were carried out where both the peptide COM and relative Arg side chain guanidinium carbon position were biased to produce the 2D PMF, $W(z, s)$. The 1D PMF $W(z)$ was then obtained by integrating $W(z, s)$ over the second variable s using Eq. (46). In similar analog simulations the equilibrium distribution of interfacial connections was obtained through restricted phase space sampling approach (Li *et al.*, 2008a), not being complicated by side chain structural isomers.

In neutral Arg side chain simulations no membrane deformations were observed (see right-hand inset of Figure 8.4 for an example), which is a consequence of much weaker interactions (by almost an order of magnitude) with water and membrane components. Arg^0 does, however, experience dehydration from 10 water molecules in bulk water to just 1–2 in the middle of membrane. The wide rotamer distribution for Arg^0 in different regions of the membrane and the absence of interfacial connections suggests that there is no need for special sampling. However, owing to the weak interactions of neutral Arg side chain with the membrane, longer equilibration times of 4–5 ns per window were required (Li *et al.*, 2008a).

8.5.2.3 Free Energy Profiles Across the Membrane

The free energy profile for the charged Arg side chain is shown in Figure 8.4a as a red line. The barrier to cross the lipid bilayer is large, 17 kcal mol^{-1}, and climbs more steeply as the charge moves deeper into the membrane, which can be explained by greater local deformations of the membrane structure (i.e. the cost to bring in more water molecules and lipid head groups into the hydrocarbon core of the membrane). We note that the full extent of the barrier is not included in this profile because this is the PMF with a reaction coordinate that is the COM of the TM helix, allowing the guanidinium to snorkel by several angstroms. The guanidinium charge is never resting at the center of the membrane. We have shown that the barrier would climb by another 3–4 kcal mol^{-1} if the guanidinium were forced to pass through the center, as shown through a remapping and integration of the 2D PMF (not shown) (Li *et al.*, 2008a). Such a barrier was also shown to be consistent with that found for an Arg analog molecule (Li *et al.*, 2008a).

The large free energy barrier indicates that the transfer of the charged Arg side chain across the lipid bilayer is highly improbable. From the slope of these free energy profiles, it can be estimated that a conformational change in a protein that requires the movement of a single Arg side chain from across the hydrophobic core must overcome a force of over 1 kcal mol^{-1} Å^{-1}, requiring the equivalent of over 1 V across the membrane (Dorairaj and Allen, 2007). This is an order of magnitude greater than physiological values and argues against any model of voltage gating of ion channels that requires a charged Arg side chain to reside or move into the hydrocarbon core of the lipid membrane.

The focus on the charged state of Arg was a result of the very high aqueous pK_a of that amino acid, because it is known that Arg does carry charge during voltage-gated ion channel activation. Yet, having excluded the possibility of "paddle"-like motions, we now question the assumption that Arg would remain protonated. Perhaps deprotonantion is a possible cause for low experimental observations in recent translocon experiments? The calculation of pK_a requires the computation of the free energy profile for the neutral Arg side chain. The Arg^0 PMF is shown in Figure 8.4a as a blue curve and exhibits a 10 kcal mol^{-1} barrier. While this is smaller than for the charged species, it is still prohibitively large, owing to the energetic costs of losing hydrogen-bonds for the neutral guanidine (Li *et al.*, 2008a). The profile for the neutral species is also different in shape, displaying a plateau instead a sharp peak. This again is a result of the lack of membrane deformations and their energetic costs.

8.5.2.4 **pK_a Profiles Across the Membrane**

On the basis of PMFs for both the charged and neutral Arg side chain, its pK_a shift profile across a lipid membrane was calculated using a thermodynamic cycle and Eq. (56). The ΔpK_a profile is shown in Figure 8.4b and remains close to 0 throughout the membrane, dropping by just ~4.5 units within a few angstroms from the membrane centre. Taking into account its high aqueous pK_a (12–13.7), this indicates that Arg remains protonated throughout the membrane at pH 7. The relatively small pK_a shift for the Arg side chain in the membrane core is owing to membrane deformations preferentially stabilizing the charged state. In the absence of such deformations the pK_a shifts would be several times greater as shown by using implicit membrane calculations as well as by extraction of the contributions from displaced water molecules and lipid head groups (see below) (Vorobyov *et al.*, 2008).

Alternatively, the ΔpK_a profile could, in principle, be obtained using FEP for Arg deprotonation at different positions across the membrane. This approach was recently used by us and others (Yoo and Cui, 2008) to calculate pK_a values inside a lipid bilayer to obtain some consistent results. However, we concluded that the convergence of membrane deformations for partially charged species in the FEP simulations was uncertain, favoring the thermodynamic cycle approach above (Li *et al.*, 2008a; Li *et al.*, 2008b).

8.5.2.5 **Thermodynamic Decomposition**

To better understand the mechanism of Arg permeation across the membrane, various approaches were used to calculate contributions to free energy profiles. IE calculations between different components of the system, both direct (such as solvent-protein and lipid-protein) and indirect (such as solvent–lipid, lipid–lipid, solvent–solvent) revealed that the energetics of Arg side chain transfer across the bilayer is a balance of very large contributions that do not completely cancel and thus can explain some part of the free energy barrier. Direct energy contributions $U_D(z, \mathbf{R})$ lead to forces, acting on the reaction coordinate z, whereas indirect energy components $U_I(\mathbf{R})$ involve interactions between other atoms and are functions of their coordinates, $\mathbf{R}$, only. For instance, the reduction in the strength of direct interactions with solvating molecules near the membrane center was observed, which would contribute to the large free energy barrier. The indirect energy calculations revealed large strain energies across the bilayer core, which resist deformations extending to the membrane center. However, energy contributions account only for a fraction of the overall free energy profile. The other, entropic component was found to be equally important for shaping overall PMF profiles, owing to the cost of immobilizing water molecules and lipid head groups solvating Arg in the membrane (Li *et al.*, 2008a).

The large contribution from entropy tells us that one must compute free energy contributions and not just energetic values. Using the relationship with the mean force (Eq. (40)), we computed contributions from lipid head groups and water molecules that are located within the membrane core ($|z| \leq 13$ Å) as a function of z to understand how the deformed membrane is assisting in the stabilization of the Arg side chain in a process that is clearly distinct from previous theoretical models (Dorairaj and Allen, 2007). Figure 8.5 reveals that hydrocarbon core-located water molecules stabilize ArgH^+ by up to 35 kcal mol^{-1} near the membrane center (red curve) because water molecules are efficient in stabilizing charges away from the aqueous phase (Allen *et al.*, 2004a). Lipid head groups (blue curve) provide up to 5 kcal mol^{-1} stabilization near the outer core but contribute ~15 kcal mol^{-1} less near the membrane center resulting in net destabilization despite their large attractive interactions with the Arg side chain (Dorairaj and Allen, 2007), thus emphasizing the difference between energy and free energy components. This destabilization results from the significant strain energy owing to bilayer deformations necessary to allow Arg–lipid head group interactions (Dorairaj and Allen, 2007). This profile is interesting in that it suggests membrane proteins may leave the Arg side chains at the membrane interface and lipid phosphates will coordinate and stabilize the protein, but that such interactions when Arg is placed deeper in the membrane are clearly destabilizing and thus not favored. By subtracting these contributions from the total PMF, a "remainder" component was obtained, which exhibits a barrier of 36 kcal mol^{-1} and represents contributions from the bulk solvent and unperturbed lipid bilayer (Dorairaj and Allen, 2007; Li *et al.*, 2008a). This can be

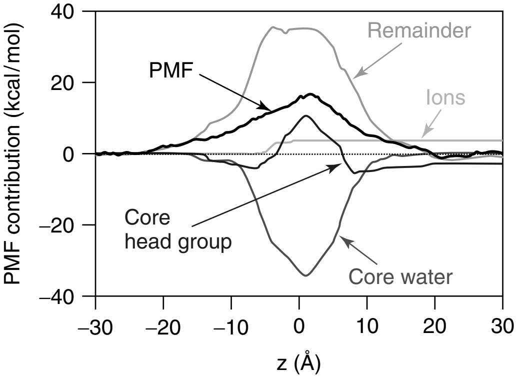

Fig. 8.5 Free energy decomposition for an Arg side chain across the membrane. The black curve is the PMF from Figure 8.4, the red curve is the contribution from water molecules inside the membrane core, the blue curve is from lipid head groups drawn into the core and the green curve is the remainder that makes up the total PMF. (adapted from (Li *et al.*, 2008a)). (Please find a color version of this figure on the color plates.)

viewed as the dielectric barrier of the unperturbed membrane some contribution from the bilayer dipole potential, as well as consistent with continuum estimates (Li *et al.*, 2008a; Vorobyov *et al.*, 2008). This calculation also demonstrates that without the membrane deformation the barrier for the charged species would be ~20 kcal mol^{-1} higher and would effectively eliminate the possibility of Arg carrying charge in a membrane.

8.5.2.6 **Accuracy of Force Fields for Arg–Membrane Interactions**

MD simulations using empirical all-atom CHARMM force field have been used to map out the thermodynamics of Arg side chain as a function of both position and protonation state across a membrane. However, since biomolecular force fields rely on empirical parameters, they are not expected to work in all cases, especially for situations not envisaged during original parameterization such as the modeling of a lipid-exposed ionizable Arg side chain. The accuracy of calculated free energy and $\mathrm{p}K_\mathrm{a}$ profiles was estimated by employing model systems to measure thermodynamics of Arg–membrane interactions using CHARMM force field and compare them to available experimental and QM data (Vorobyov *et al.*, 2008).

Solvation free energies of both charged and neutral Arg side chain analogs (propyl and methyl guanidinium and guanidine) in water and cyclohexane as well as partitioning free energies between these liquids were obtained by performing FEP simulations of these models in bulk solvents using *NPT* MD runs with PBC and in the gas phase using Langevin dynamics (Vorobyov *et al.*, 2008). The linear coupling scheme was used for electrostatic and dispersion free energy components, whereas the repulsive term was transformed into a soft-core potential and calculated in multiple stages using recently developed protocol (Deng and Roux, 2004). The calculated free energies were corrected for the dipole potentials of the corresponding interface (water–air, cyclohexane–air, and water–cyclohexane) and periodicity artifacts for the charged species (Vorobyov *et al.*, 2008). Calculated solvation and partitioning free energies were then compared to experimental values (if available) or estimates from continuum solvation models. CHARMM estimates of hydration free energies for both charged and neutral Arg side chain analogs were within ~1 kcal mol^{-1} of corresponding reference values (e.g. −62 kcal mol^{-1} for MGuanH^{+} and −11 kcal mol^{-1} for MGuan^{0}). Solvation free energies of neutral Arg side chain analogs in cyclohexane and their water–cyclohexane partitioning free energies are also in good agreement (within 1 kcal mol^{-1}) with experimental data (Vorobyov *et al.*, 2008). However, the lack of the electronic polarizability in this force field caused substantial underestimation of solvation free energies of the charged Arg side chain analogs in cyclohexane and thus overestimation of their unfavorable water–cyclohexane partitioning energetics by ~20 kcal mol^{-1} (Vorobyov *et al.*, 2008). FEP simulations of these ions using a recent Drude polarizable cyclohexane model (Vorobyov *et al.*, 2007) provided solvation and partitioning free energies close to values predicted by continuum solvation models, around −30 and 30 kcal mol^{-1}, respectively (Vorobyov *et al.*, 2008). However, by comparing relative energies of different system configurations with and without Drudes, this effect was found to be substantially smaller (on the order of 1 kcal mol^{-1}) for Arg side chain or analog transfer across the bilayer owing to their shielding from hydrocarbon lipid tails by water molecules and lipid head groups (Dorairaj and Allen, 2007; Vorobyov *et al.*, 2008).

To estimate the effect of polarizability on these PMF profiles directly we also carried out umbrella sampling MD simulations of MguanH^+ across the bilayer core with Drude particles on lipid hydrocarbon tails (Vorobyov *et al.*, 2008). These simulations were performed using 1 fs time step and the extended Lagrangian formalism by assigning small atomic masses of 0.4 amu to Drude particles and keeping them at low temperature of 1 K with a separate thermostat (Lamoureux and Roux, 2003). Two separate simulations for each window were run: starting with nonpolarizable CHARMM equilibrated configurations where bilayer deformations were already present or deformation-free initial structures. Interfacial connections with MguanH^+ in the membrane core (similar to those observed with a nonpolarizable membrane) were established and/or remained stable during the course of simulations. The resultant free energy profiles are very similar to that from the nonpolarizable CHARMM MguanH^+ simulation with the barrier lower by 1 kcal mol^{-1} (Vorobyov *et al.*, 2008). This confirms a surprisingly small effect of lipid polarizability on PMF despite much larger effect on water–hydrocarbon partitioning energetics and also substantially lower dipole potential for the polarizable lipid model (around 550 mV vs. 900 mV for the nonpolarizable lipid). The membrane deformations shield Arg side chain from interactions with lipid hydrocarbon and also prevents it from seeing the full extent of the dipole potential.

It was also necessary to determine how accurately CHARMM accounts for interactions of the Arg side chain with coordinating water molecules and lipid head groups, which drive the membrane deformations. This was done by comparing CHARMM and QM IEs for the corresponding clusters extracted from umbrella sampling simulations of ArgH^+ and Arg^0 models. Arg side chains were transformed into MGuanH^+ or MGuan^0, respectively, whereas lipid phosphate moiety was turned into dimethyl phosphate anion (DMPA). Water molecules within the first solvation shell of both MGuan and DMPA (within 3 Å) were kept. CHARMM IEs between Mguan, DMPA, and water were calculated using infinite cutoffs for nonbonded interactions. In QM calculations ten clusters for a pair of adjacent umbrella sampling windows were used with the most typical number of water molecules (six for charged and seven for neutral Arg) and CHARMM IEs closest to the average values. QM IEs used as reference values were calculated with Gaussian03 (Frisch, 2004) at the MP2/6-31+G(d) level and corrected for the basis set superposition error (BSSE) using the counterpoise technique (Boys and Bernardi, 1970). Both CHARMM and QM results were averaged for different regions of the membrane (interface, central and outer core) where Arg side chain was located. IEs between MguanH^+ and dehydrated DMPA are underestimated by CHARMM by ~7 kcal mol^{-1}, whereas those between MGuanH^+ or MGuan^0 and water clusters are overestimated by ~4 or ~5 kcal mol^{-1}, respectively. The interactions between MGuanH^+

or MGuan^0 and hydrated DMPA (i.e. DMPA/water clusters as one unit) are also made too attractive by CHARMM by ~6 kcal mol^{-1} (Vorobyov *et al.*, 2008). This is expected since nonpolarizable CHARMM force field was parameterized to reproduce condensed phase where ion–ion interactions are weakened and ion–solvent might get stronger compared to gas phase owing to cooperativity effects. Thus in nonpolarizable CHARMM, where these effect modeled implicitly, for example through enhanced dipole moments, the gas-phase behavior is inevitably sacrificed. The effect of these errors on PMF can be calculated using FEP formalism:

$$\Delta G = -kT \ln \left\langle e^{-\Delta U/kT} \right\rangle_{(\mathrm{CHARMM})} \quad (70)$$

where ΔU here is the difference between QM and CHARMM IEs for each configuration. For interactions between MguanH$^+$ or Mguan^0 and DMPA/water clusters, these ΔG and thus errors in free energy profiles are just 1.6 or 2.5 kcal mol^{-1}, respectively (i.e. CHARMM free energy barriers are too low), and are fairly constant across the membrane (Vorobyov *et al.*, 2008). The much smaller ΔG compared with $\langle \Delta U \rangle$ can be explained in terms of the stronger interactions giving rise to higher indirect energies and entropy costs. (Vorobyov *et al.*, 2008).

We also estimated that simulation artifacts related to the use of the finite bilayer patch (periodicity artifacts), fixed surface area, finite cutoffs for nonbonded interactions affect the accuracy of PMF profiles by around 0.5 kcal mol^{-1} or less (Vorobyov *et al.*, 2008). On the basis of all these tests it can be concluded that CHARMM free energy barriers for charged or neutral Arg side chain translocation across the membrane can be trusted to 1–2 kcal mol^{-1}, whereas pK_a shift profiles are accurate to within the order of 1 unit. (Vorobyov *et al.*, 2008).

8.6
Conclusion and Prospects

This chapter has outlined some of the basic principles of MD simulation of proteins. We have concentrated on modern force fields and algorithms for protein simulations as well as methods for quantitative analysis of protein activity. Experiment has provided a wealth of insight into the structure and function of both globular and membrane proteins. However, microscopic simulation, combined with rigorous statistical mechanical techniques, can assist in uncovering some microscopic mechanisms.

Though there exists an impressive range of protein simulations published today, we chose to illustrate just two related case studies involving membrane-bound ion channels, with the goal of elucidating the mechanisms by which proteins can control the passage of charged molecules across biological membranes. To better illustrate the utility of MD simulation we have made use of model peptides, which reduces the size and complexity of the problem while making the microscopic mechanisms of interest more general and transparent. We demonstrated how computer simulation can be used to generate configurational sampling of protein systems using biased sampling protocols to calculate equilibrium free energy surfaces governing protein function. Umbrella sampling and free energy perturbation are the basic tools of MD free energy simulation that permit a chosen spatial or alchemical reaction coordinate to be sampled in a reasonable simulation time. While there are several advanced simulation techniques, barely touched upon in this review, these methodologies all offer a direct route to understanding function and making contact with experimental observables. We have also seen how free energy surfaces along several choices of protein and solvent coordinates can reveal much about the mechanisms of function, as demonstrated here for ion and solvent contributions to a permeation process. In principle, however, any array of relevant order parameters can be examined in this manner.

One of the major focuses of this review has been the design and choice of MM force fields for proteins and membrane systems. Yet our illustrations concerned interactions for which the force fields were not specifically designed. That is, while protein and membrane force fields have undergone independent parameterizations, they can be combined successfully as a result of a common underlying paramterization strategy. We went on to show that for the most challenging of situations where a charged protein side chain enters the hydrocarbon core of a membrane, interactions and solvation free energies remained accurate to the order of kT. The key feature of the solvation environment of the amino acid side chain that led to this accuracy was the penetration of water molecules to maintain a nearly aqueous environment, because force fields were developed to reproduce such environments.

However, this does not mean there are no errors in present-day force fields. We have seen that the description of nonpolar molecules, such as the hydrocarbon interior of a lipid membrane, is fundamentally flawed owing to the lacking description of electronic polarizability. The description of electronic polarizability for nonpolar molecules as well as polar molecules, in particular around sites of high charge density, is currently an active area of research. The next generation of force fields will allow us to take MD simulations of proteins to even higher levels of accuracy and better reveal hidden mechanisms of function.

9.1
Introduction

> *"Muscle is the only known piece of machinery which can be cooked in many ways." Thomas A. McMahon in Muscles, Reflexes, and Locomotion*

One defining characteristic of life is the ability to use energy to actively and purposefully transport matter against opposing forces, thus bringing the organism far away from thermodynamic equilibrium, a defining property of so-called dissipative systems (Prigonine, 1978). Matter is transported from one part of a single cell to another, from the roots to the branches of a tree, or even from our dinner plates to our mouths. Such transport depends on a complex and highly idiosyncratic interplay between thousands of different molecules in a process collectively termed *cell motility*, justly considered "one of the crowning achievements of evolution." (Lodish *et al.*, 1995) This chapter focuses only on those molecules that are most evidently involved in the movement of whole organisms, with special attention to the molecular composition of muscles and the parameters governing their molecular interactions. This chapter is mainly focused on the forces and interactions existing between only a small subset of proteins that are directly involved in muscle activation and movement (these are listed in Table 9.1), and should not be seen as a full treatment of the literature, rather it is hoped that this work will provide the reader with some general knowledge from which to initiate further explorations into the different topics covered.

When trying to describe the dynamics of individual muscle proteins, one should keep in mind that the biological systems we have access to study today are the result of a selection process that has now lasted several billion years. In this arms-race of evolution, the ability to move has played a decisive role in determining which molecular interactions give the most viable solutions. During this selection process, most of these molecules have acquired a multiplicity of roles added step by step as adaptations providing new functionality into an already working system. This ultimately implies that a single protein might be involved in many very different cellular processes due to its interaction with many different molecules. Of these proteins, myosin is by weight the most abundant protein in mammals, and it is also the protein whose function is most directly evident: to produce tensile

Tab. 9.1 Proteins involved in muscle contraction.

Protein	Abbreviation	Function
Acetylcholine receptor	ACh-R	Activation and excitability
Voltage gated Na^+ channel	vNa	
Voltage gated K^+ channel	vK	
Ryanodine receptor	RyR	Ca^{2+} binding and transport
Dihydropyridine receptor	DHPC	
Parvalbumin	par	
Calsequestrin	cal	
Tropomyosin	Tro	
Troponin C	TrC	
Troponin T	TrT	
Troponin I	TrI	
Sarco(endo)plasmic reticulum calcium ATPase	SERCA	
Titin	Tt	Scaffolding and connection
Connexin	Cx	
Actin	Ac	
Myosin	Mys	Force production

force. However, this force would never be produced were it not for several dozen other proteins responsible for activation, modulation, regulation, scaffolding, strong reversible bonding, and so on (see Table 9.1).

9.2
Organization of Muscle Cells

Muscles are collections of single cells, each of which has the ability to contract. By acting in synchrony, the small contribution generated by each cell adds up to considerable forces in the whole muscle (>50 N cm^{-2}). On a first approximation, it is precisely the organization of such cells which determines whether a muscle belongs to the skeletal, the cardiac, or the smooth muscle type:

- Skeletal muscle: These are highly organized into sarcomeres with all muscle fibers arranged in parallel and pulling synchronously. Skeletal muscle fibers are activated by synapses using the neurotransmitter acetylcholine, and are under voluntary control.
- Cardiac muscle: The muscle fibers are organized into sarcomeres, with individual fibers arranged in parallel. Cardiac muscle cells are connected with gap junctions so that an electric pulse generated at one place (the sinoatrial node) will propagate throughout the cardiac muscle through such junctions. These pulses are myogenic (self-initiated) and do not require direct synaptic activity, but are modulated by sympathetic and parasympathetic nervous activity.
- Smooth muscle: The filamentous muscle proteins are not organized into sarcomeres, and may be activated either by cell–cell propagation through gap junctions, via synaptic action or via hormonal effects. The

spindle shaped smooth muscle cells respond to autonomic control and to hormonal stimulation.

In the following, we specifically consider the skeletal muscle type, keeping in mind that there are significant differences to the other muscle types. However, it can be argued that these differences are more of a structural nature, and thus a quantitative biophysical model of muscle should, by its nature, be adaptable to any of the possible muscle types insofar as it contains the right type of parameters.

A single cell in a muscle is known as a *muscle fiber*, and in addition to all the usual organelles present in animal cells (e.g. nucleus, mitochondria, and Golgi apparatus), it predominantly houses the sarcoendoplasmic reticulum (SR) enveloping several myofibrils (mfs). SR and mfs dominate the muscle fiber almost to the point of excluding other organelles. As will be clarified shortly, the division of labor is such that the SR transforms the electric signals from the nerves and T-tubule system into Ca^{2+} signals within the mfs, whereas the mf is responsible for the production of mechanical force and subsequent contraction.

9.3
Sequence of Events Leading to Muscle Contraction

Motor neurons in the spinal cord innervate muscle tissue are therefore the only major class of neurons that make synaptic contact with non-nervous tissue. A distinction is made between α, β, and γ type motorneurons, depending on the actual type of muscle tissue that they contact. By definition, α motor neurons in the spinal cord directly synapse with muscle fibers whereas γ type neurons activate contractile tissue within the muscle spindle (a sensory organ within muscles that monitors rate of change of length and tension in the muscle). Beta Motor neurons innervate both types of fibers.

When an action potential arrives at the neuromuscular junction, small packets of the neurotransmitter acetylcholine (ACh) are released from the presynaptic region of the neuromuscular junction. Each released packet (or vesicle) contains on the order of 10000 ACh molecules, which diffuse across the narrow synaptic gap separating the motor neuron from the muscle cell, and subsequently bind to postsynaptic acetylcholine receptors (ACh-R). Each molecule of ACh is capable of binding to a single ACh receptor only once before it becomes hydrolyzed into acetate and choline (by acetylcholinesterase, an enzyme in the synaptic cleft), but two molecules of ACh are required to effectively activate the receptor.

Thus, the ACh-R is the first protein that becomes activated upon binding of neurotransmitter initially released following the arrival of an action potential to the neuromuscular junction. When ACh binds to the receptor the associated nonspecific ohmic ion channel opens, creating a small conductance $g_{\mathrm{ACh}} \sim 30$ pS and the ensuing current, I_{ACh}, will drive the local membrane potential, V_m, toward the reversal potential for the ion channel, $E_{\mathrm{ACh}} = 0$ mV. Formally the current through the ion channel may be expressed as

$$I_{\mathrm{ACh}} = g_{\mathrm{ACh}}(V_m - E_{\mathrm{ACh}}) \qquad (1)$$

Given that muscle cells typically have a resting membrane potential of approximately $V_m = -90$ mV inside relative to outside, a depolarization toward the reversal potential of the acetylcholine receptor will effectively cause an influx of positively charged ions that are driven by the electrochemical gradient, primarily of Na^+ initially. The "cloud" of acetylcholine released from a single presynaptic spike is typically responsible for activating on the order of 10^5 individual ACh-receptors, resulting in a total current of approximately -500 nA (by convention currents are measured as outward positive). This current causes a buildup of charge across the muscle cell's membrane, which effectively functions as an insulator with a specific capacitance of $1\,\mu F\,cm^{-2}$ and a specific resistance of $20-60\,k\Omega\,cm^{-2}$ (roughly equivalent to an RC-circuit with a time constant of 20–60 ms). When the electric field across the membrane reaches a certain threshold (usually 10–20 mV above the resting membrane potential), another class of membrane proteins are poised for action to initiate an action potential in the muscle cell, namely the voltage-gated Na^+ and K^+ channels. Given the electrochemical gradients of Na^+ and K^+, the former type of channels will activate quickly to further depolarize the membrane by initiating a positive feedback loop in which depolarization leads to more Na^+ channels opening, Na^+ ions flow into the cell thus giving further depolarization, until the reversal potential for Na^+ is reached around $> +30$ mV. Conversely, the later (K^+) channel will be activated at a higher threshold and with a short time delay and will drive the membrane toward the reversal potential for K^+ (at around -90 mV) due to the resulting efflux of K^+, ultimately reaching the resting membrane potential.

This results in a wave of depolarization called a *muscle action potential*, an event that is very similar to the action potential observed in neurons and other excitable cell types. However, the muscle action potential will not result in the release of neurotransmitter, instead it will result in the contraction of the muscle fiber. The muscle action potential propagates deep into the muscle fiber via the T-tubule network, see Figure 9.1, where it activates dihydropyridine receptors (DHPRs). These are a specialized type of voltage dependent L-type Ca^{2+} channels that exist within the T-tubule membrane of all muscles (see reviews by Franzini-Armstrong (1999); Dulhunty *et al.* (2002)) and respond to the incoming wave of depolarization by opening a Ca^{2+} selective ion channel and/or by interacting directly with the ryanodine receptor (RyR), a protein embedded in the membrane of the SR, reviewed in Fill and Copello (2002). The amount of Ca^{2+} released from the extracellular fluid into the myoplasm via DHPR channels is not sufficient to activate muscles by itself, an additional release of Ca^{2+} is required (see reviews by Bottinelli and Reggiani (2000); Dulhunty *et al.* (2002). In cardiac muscle, the RyR channel becomes activated directly by the Ca^{2+} released through the DHPR channel (Nakai *et al.*, 1996; Gurrola *et al.*, 1999; Protasi *et al.*, 2002; Kugler *et al.*, 2004); however, in skeletal muscle an additional direct molecular interaction between DHPR and RyR is required to activate the RyR channel (Bottinelli and Reggiani, 2000). In either case, the release of additional Ca^{2+} into the myoplasm is mediated by the activation of the RyR channel, which in fact is a Ca^{2+} selective ion channel that permits the release of substantial amounts of Ca^{2+} from the internal buffers within the lumen of the SR, primarily from

Fig. 9.1 Activation scheme for a muscle, emphasizing the role of proteins in the process of muscle contraction. "Clouds" of dots indicate the presence of freely diffusing substances like neurotransmitters and Ca^{2+}, stars indicate direct contact based protein–protein interaction, arrows indicate transport or diffusion gradient, dashed lines indicate the membranes of different cellular compartments within muscle cells, and rounded squares are actual proteins. Numbering roughly corresponds to activation order in the muscle activation sequence. Abbreviations used are SNARE, soluble N-ethylmaleimide sensitive fusion protein attachment receptor; ACh, acetylcholine; DHPR, dyhydropyridine receptor; RyR, ryanodine receptor; trC, troponin C; trI, troponin I; trT, troponin T; SERCA, sarco(endo) plasmic reticulum calcium ATPase. See text for further details on the activation dynamics.

calsequestrin (csq) (Jorgensen, Kalnins and MacLennan, 1979; Jorgensen *et al.*, 1983; Beard, Laver and Dulhunty, 2004). Once Ca^{2+} is present in the myoplasm, it will either be sequestered by endogenous buffers or it will bind to Troponin C (trC) which by direct molecular interactions will cause conformational changes in troponin I and troponin T, and tropomyosin (see Collins (1991); Alberts *et al.* (2002) for review), ultimately leading to a small displacement of tropomyosin relative to the actin filament around which it is intertwined. The resting function of tropomyosin, that is, when no Ca^{2+} is present, is to block specialized binding pockets where the actin binding region of the myosin molecule will bind in the presence of ATP, so when Ca^{2+} is present, these binding sites will be available for myosin and contraction may begin. It should be noted, that in some types of muscle fiber (e.g. fast fatigable fibers) relatively high concentrations of buffer proteins are present in the myoplasm, especially parvalbumin (par) which assists in rapidly sequestering Ca^{2+} from the myoplasm, leading to contractions of shorter duration due to the shorter exposure time of Troponin to Ca^{2+} (Celio and Heizmann, 1982).

Once bound to actin, the neck region of myosin will undergo a conformational change in which it will cause the myosin head region to rotate approximately 90°, essentially shortening the end-to-end distance of the myosin molecule (Lymn and Taylor, 1971; Holmes, 1996). This conformation change thus produces a force that induces a translation of actin with respect to myosin, subsequently transmitted via connective proteins such as α actinin, capZ, nebulin (nebulette), and connectin (titin) to neighboring sarcomeres, ultimately causing a contraction of the whole muscle fiber.

9.4
On the Forces Produced by an Array of Springs

The smallest functional unit in muscle is the sarcomere, a structure which in mammals has a typical diameter of approximately 1 μm, and length between 1.5 and 3.5 μm, depending on the state of contraction (and type of muscle). Within the sarcomere, thick filaments composed of myosin and thin filaments composed of actin are arranged in parallel so that each thick filament is surrounded by exactly six actin filaments. A cross section of this system reveals a clearly hexagonal pattern. The cross-sectional area of such a hexagon is $\sim 1200\,\text{nm}^2$, so approximately 650 thick filaments contribute to force in a single sarcomere. Along the thick filament two pairs of myosin heads are found sticking out in opposite directions every 14.3 nm, and each such opposing group of myosin molecules is rotated 60 °C with respect to the preceding group. The myosin head covered region of the sarcomere can be calculated from the typical length of the A-band (anisotropic band) minus the typical length of the H-band (bright band), which gives approximately 1.4 μm. Note, that two halves of a sarcomere are separated by the H-band and pull in opposite directions, so effectively the working unit is the half sarcomere. The total number of working myosin head pairs spanning one half of the sarcomere on a single thick filament can thus be calculated to be $2 \times 700\,\text{nm}/14.3\,\text{nm} \sim 100$. When attached to actin, a single myosin head produces forces in the range of 1–10 pN, thus a quick calculation reveals that if one assumes all myosin heads are simultaneously active, the maximal holding force that a single thick filament can produce in one direction will be in the range of 0.1–1 nN, and the total force that may be produced by a single muscle may be estimated from its cross-sectional area, ranging approximately from 8 to $80\,\text{N cm}^{-2}$. Although the origin of this force is generally accepted to be in compliance within the actomyosin complex, the exact details pertaining to how the force production is initiated and maintained remain the subject of intense study (for a recent review and account see Karatzaferi, Chinn and Cooke (2004). Much attention has been given to determining how and when the energy released from the hydrolysis of a single ATP molecule ($\sim$0.06 aJ or $36\,\text{kJ mol}^{-1}$) brings about the appropriate conformational changes of the myosin neck and head regions. Some hints may be gained by examining the details of myosin–actin interactions. In fact, at any given time only a fraction of the myosin heads are attached to actin and therefore contribute to force. Myosin goes through an attachment–detachment cycle known as the *cross-bridge cycle*. Within this cycle, myosin has two preferred conformations, one when bound to ATP and one when bound to ADP, distinguishable by the angle between the myosin neck–head region with respect to the main trunk of the thick filament. When bound to ATP, myosin detaches from actin and the preferred conformation is one where the myosin molecule as a whole is more contracted, with an angle of about 45 °C between the myosin tail and the myosin neck–head region. Myosin is an ATPase and will therefore break down ATP into ADP + P, but this must occur in several steps. First a complex of ADP·P is formed during which the preferred conformation of myosin changes to be much more extended, with the neck–head region of myosin now forming an angle of 90 °C to the myosin tail. At this position, the actin binding site on the myosin head comes into perfect apposition to the myosin binding sites on the actin filament, and a weak bond is formed. Once bound, phosphate is released from the ADP·P complex, and the preferred conformation of myosin changes back to the 45 °C configuration; however, this change cannot occur immediately because at this point actin is bound to the myosin head, and must be pulled from its current position to a position corresponding to the new preferred conformation of myosin. This rotation of the myosin head causes a 5.3 nm displacement of the myosin filament with respect to the actin filament, and the amount of work produced by this rotation will be calculated in the next paragraph.

Detailed biophysical models of this system have been developed and carefully described in several articles and books, and the reader is encouraged to consult these for further details, especially (McMahon, 1984; Bagshaw, 1994). What follows here is a highly simplified model that captures only the bare essentials, to give a sense of the type of information such models require and provide. Given the highly organized almost crystalline structure of muscle, it is straightforward to produce a simple model of force production. It seems certain that all active crossbridges within a half sarcomere will act in parallel, so their individual contributions are additive. To keep things simple assume that each myosin–actin crossbridge acts like a spring with an extension dependent spring force, $s(x_i)$, where x_i is the extension of the particular crossbridge indexed by i. Assuming that there are N crossbridges formed, the total force, F_{tot}, produced by such an array of parallel springs amounts to

$$F_{\mathrm{tot}} = \sum_{i=1}^{N} s(x_i) \tag{2}$$

It is here assumed that all bonds form at an initial extension length of approximately $x = 5.3$ nm, and during muscle contractions these bonds shorten until bond release occurs at $x = 0$ nm, while during muscle stretching these bonds lengthen until bond breaking at approximately $x = 11$ nm (in agreement with experimental evidence reported in Brown and Loeb (1999)). Hence, during contraction the crossbridge will have contracted from $a = 5.3$ nm to $b = 0$ nm, producing the total work $W_{\mathrm{tot}} = \int_a^b s(x)dx$. For simplicity a linear spring model has most predominantly been used in the literature to represent the compliance of the myosin–actin cross-bridge, thus $s(x) = kx$, although the actual origin of this force has not to date been properly specified. In this case the total work of contraction becomes $W_{\mathrm{tot}} = \frac{1}{2}\mathrm{ka}^2$, which for a spring with $k = 2$ pN nm^{-1} amounts to 0.028 aJ of work (vs. 0.06 aJ for ATP hydrolysis). By a similar argument, the amount of work required to stretch the bond from initial state of 5.3 nm to bond breaking point at 11 nm is approximately 0.09 aJ. From the point of view that the force producing region is in fact a polypeptide that is folded in a particular way, it would be reasonable to assume the compliance to be nonlinear, perhaps following the force-extension profiles described for other polypeptide systems (as proposed by Howard and Spudich (1996); Nielsen (2002)). Actual stretching experiments on this system have proven difficult to perform, and therefore only a limited amount of experimental data is available. Experiments by Molloy *et al.* (1995); Lewalle *et al.* (2008) support the linear compliance view, even though in these experiments myosin exists under rather unnatural conditions as single filaments bound to very large spheres. In reality myosin exists within a rather constrained environment, and it is difficult to evaluate how this constrainment affects functionality. Stretching experiments performed *in silico* using steered molecular dynamics reveal that the form of the force-extension profile of a single scallop myosin molecule (in rigor) to some extent depends on the velocity of stretching, see Figure 9.2b. Although very approximative, this result hints to the fact that effects such as friction, damping, geometric constraints and hydrostatic forces might also have a role to play under nonisometric conditions.

Thus, to a first approximation, the myosin-actin crossbridge seems to have a linear force-extension relationship within the extension range relevant for muscle contractions, the remaining question is then: where does this linearity come from? Given that myosin is a complex polymer molecule that is being mechanically deformed one would expect that entropy and Brownian motions to a large extent dictate the forces present at the force producing neck region of myosin, similar to what has been described for many other proteins and polypeptides (Smith, Finzi and

Fig. 9.2 Stretching experiment performed *in silico* using steered molecular dynamics in order to apply controlled forces on different parts of a myosin molecule. (a) The myosin molecule was stretched out to a predetermined extension and then held at that position to sample the reactive force produced by the molecule. The colored blobs indicate force-extension samples resulting from five different stretch–hold experiments. A line fitting these samples is shown together with a family of dashed lines corresponding to best fits using the worm like chain model expressed by Eq. (3) and using persistence lengths from 2 to 5 Å, and contour lengths of 20–40 nm (explanation in text). (b) The molecule was continuously stretched at a high velocity and the reactive force was plotted. The best fit worm like chain model is also shown as a black line. In both cases coordinate data corresponding to scallop myosin in near rigor state was obtained from the Protein Data Bank (pdb-id: 1SR6), from which a sub region was selected to represent the neck region of the molecule, corresponding to residues 473–584, 693–728, and 738–781, and shown in the figure as the first molecular structures surrounding the plots (upper left structure). This subregion was equilibrated using molecular dynamics (NAMD2 developed by Kalé *et al.* (1999), and a number of α carbon atoms was fixed while the α carbon of residue 774 was pulled in different directions depending on the case, either as a stretch–hold experiment (a) or constant velocity pulling experiment (b), resulting in the other molecular structures shown. (Please find a color version of this figure on the color plates.)

Bustamante, 1992; Bustamante *et al.*, 1994; Kellermayer *et al.*, 1998; Smith and Radford, 2000; Marszalek *et al.*, 1999; Rief *et al.*, 1999; Oberhauser *et al.*, 1998). Hence, the apparent linearity of myosin must be derived from a first principles perspective and not just accepted without question. One possible scenario which would allow for linearity at short extension ranges while still maintaining an entropy driven folding process, makes use of the so-called Worm-Like Chain model of polypeptides (initially developed for DNA by Marko and Siggia (1995)). Within this model, statistical mechanics are used to describe the thermodynamic forces affecting a polymer by assuming that the polymer can be approximated by a flexible chain consisting of linked units (here amino acids). The model predicts that a linked flexible chain in a thermal bath will have a natural tendency to fold up to minimize free energy, thereby maximizing entropy. Work done on such a chain will reduce its entropy until the chain is fully stretched, and the force required to perform this work depends on the extension of the polymer, and although the actual derivation is rather involved (see derivation by Marko and Siggia (1995), the resulting expression is in fact quite simple:

$$s(x) = \frac{k_B T}{A}\left(\underbrace{\frac{x}{L} - \frac{1}{4}}_{\text{linear}} + \underbrace{\frac{1}{4\left(1 - \frac{x}{L}\right)^2}}_{\text{nonlinear}}\right) \tag{3}$$

where k_B is Boltzmann's constant, T is the temperature, A is the persistence length of the chain (equal to one half the Kuhn length of the chain, b, the length of the freely jointed links in the chain), x is the amount of extension away from the unperturbed state, and finally L is the contour length of the chain (i.e. the unfolded length of the polymer under consideration). The contour length is here related to the persistence length as $L = Nb = 2NA$, where N is the number of links making up the polymer. Substances obeying this type of force-extension relationship are said to possess *entropic elasticity*, and behave linearly at extensions much smaller than the length of the folded region of polymer, but nonlinearity at greater extensions. Figure 9.2a shows a family of force-extension curves (dashed lines) showing a range of persistence lengths from 2 to 5 Å, and contour lengths of 20–40 nm. Note here that within the extension range relevant for muscles (0–11 nm) all of these curves are close to linear. The implication here is, that the individual links in the chain are identical with the rigid peptide bond, and that steric hindrances imposed by side chain protruding from the C_α atoms lead to further rigidity resulting in a Kuhn length which is very close to 0.7 nm, and thus corresponding to the length of a dipeptide. The further implication is that the number of peptide bonds participating in the contour length should be in the range of 30–60, given that the contour length is about 20–40 nm. This compares well to the apparently deformable region observed during molecular dynamics simulations, and is not a bad estimate given the almost naive simplicity of this model. Further details about how these results have been obtained will be published elsewhere.

The next step is to define the form and appropriate values for the distribution of crossbridge extensions represented by x_i. In one approach (developed further in Nielsen (2002)), it is assumed that during contraction there is a uniform distribution of lengths between $a = 0$ and $b = 5.3$ nm, thus $x_i = x_1, x_2, \ldots, x_{n-1}, x_n = \{\delta, 2\delta, 3\delta, \ldots, (n-1)\delta, 5.3\}$, where $\delta = (b - a/N_{\text{cb}})$ thus the total force produced by the system can be found as the integral sum over the forces for all the different lengths:

$$F_{\text{tot}} = \frac{N_{\text{cb}}}{b-a} \int_a^b s(x)dx \tag{4}$$

which assuming $s(x)$ has the form given by Eq. (3) gives the total force:

$$F_{\text{tot}} = \frac{N_{\text{cb}}}{b-a} \int_a^b \frac{k_B T}{A} \times \left(\frac{x}{L} - \frac{1}{4} + \frac{1}{4(1-\frac{x}{L})^2}\right) dx \tag{5}$$

$$= \frac{N_{\text{cb}}}{b-a} \frac{k_B T}{A} \left(\frac{b^2 - a^2}{2L} - \frac{1}{4}(b-a) \right. \tag{6}$$

$$\left. + \frac{L}{4}\left(\frac{1}{1-b/L} - \frac{1}{1-a/L}\right)\right) \tag{7}$$

The remaining task is to determine the actual number of crossbridges that have formed and to this end it is useful to consider, that bond formation takes time, and that the amount of available time falls off linearly as a function of sliding velocity between filaments. At increasing velocity there must be a trade off between the increased frequency with which myosin heads encounter actin binding sites, and the reduced time available for interaction. A simple scheme to describe this considers the probability that a bond actually forms as a simple linearly decreasing function of velocity:

$$p_{\text{bond}} = 1 - \kappa \frac{|v|}{v_{\max}} \tag{8}$$

Where κ is a muscle dependent parameter, and $v_{\max}$ is the maximal sliding velocity of the muscle. One of the cornerstones in experimental muscle science was the observation by Hill (1938); Hill (1964), that the force of a muscle and its corresponding contraction velocity seem to follow a very simple hyperbolic relationship given by $F_{\text{hill}} = (1 - v)/[1 + v/k)]$, where k is a parameter that depends on the muscle type in question (typical values are in the range from 0.15 to 0.25). Any muscle model should as a minimum be able to account for this result, and the very simple approach adopted here does indeed lead to similar results (see e.g. Nielsen (2002); Nielsen (2003)). Furthermore, one should always consider the ATP utilization rate and the rate of energy liberation predicted by a model, and again the results here compare quite nicely with experiment (as reported in Nielsen (2002)). Thus we may assume that the main ingredients of muscle contraction have been captured by the model. Further refinements are of course necessary to truly claim that this model describes muscle accurately, for example, one should consider the duty ratios of myosin more carefully, and also it would be necessary to include many of the compliances acting in series with the muscle section considered here. Furthermore, the binding rates of myosin to actin may be included in much more detail (as has been done by other workers, see e.g. Zahalak (2000); Huxley (1957); Ford, Huxley and Simmons (1977)).

9.5
Activation Dynamics

Most proteins listed in Table 9.1 are involved in Ca^{2+} binding and Ca^{2+} transport within muscle tissue, and are crucial to muscle activation and dynamics but do not participate in the generation of force as such. Muscles are traditionally considered as part of the nervous system in lieu of their very close interaction with neurons and their intrinsic excitability. This excitability is mainly caused by the activation of voltage-gated Na^+ and K^+ channels, and is initiated by the opening of acetylcholine receptors. What really sets muscle cells apart from other excitable cells is the cascade of molecular events following excitation. As mentioned in a previous section, and hinted at in Figure 9.1, depolarization leads to activation of the DHPR, and subsequently to release of calcium from the sarcoplasm through RyR. The exact details depend on the muscle type in question, but regardless of type and mechanism, it is useful to consider the movement of Ca^{2+} through the system as such. If we assume that Ca^{2+} is a limited resource within the cell, then one may keep track of Ca^{2+} by determining which of the proteins in Table 9.1 act as sinks and/or sources of Ca^{2+}, and which of the compartments in the muscle cell are to be considered Ca^{2+} reservoirs. In brief, Ca^{2+} may be said to exist either as free Ca^{2+} or as buffer bound Ca^{2+}. Working through the detailed description given previously on Ca^{2+} movement and summarized in Figure 9.1, the following fractions of Ca^{2+} may be considered:

φ_{myo}	Free Ca^{2+} within the myoplasm
φ_{sar}	Free Ca^{2+} within the longitudinal regions of the sarcoplasm
φ_{csq}	Ca^{2+} associated with calsequestrin or diffusing freely in the sarcoplasmic terminal
φ_{trc}	Ca^{2+} in association with troponin C
φ_{par}	Ca^{2+} in association with parvalbumin (=0 in slow-twitch fibers)

Given that these are fractions of the total amount of calcium, their sum must be unity. To describe sudden movement of a certain fraction, ε of calcium moving from one reservoir, a to another, b, at time t_0 simple equations may be used of the form:

$$\frac{d\varphi_a}{dt} = \frac{\varphi_b}{\tau} - \varepsilon\varphi_b\delta(t-t_0) \tag{9}$$

$$\frac{d\varphi_b}{dt} = -\frac{\varphi_b}{\tau} + \varepsilon\varphi_b\delta(t-t_0) \tag{10}$$

where τ is a time constant controlling the rate of movement of Ca^{2+} from reservoir b to reservoir a. One such equation is needed for each suggested Ca^{2+} reservoir. Considering the interaction network presented in Figure 9.1, six time constants are considered rate limiting in the present model:

τ_{csq}	Time constant governing $\varphi_{\text{sar}} \rightarrow \varphi_{\text{csq}}$
τ_{serca}	Time constant governing $\varphi_{\text{myo}} \rightarrow \varphi_{\text{sar}}$
$\tau_{\text{trc,on}}$	Binding time governing $\varphi_{\text{myo}} \rightarrow \varphi_{\text{trc}}$
$\tau_{\text{trc,off}}$	Dissociation time constant governing $\varphi_{\text{trc}} \rightarrow \varphi_{\text{myo}}$

$\tau_{\mathrm{par,on}}$ Binding time constant governing $\varphi_{\mathrm{myo}} \rightarrow \varphi_{\mathrm{par}}$

$\tau_{\mathrm{par,off}}$ Dissociation time constant governing $\varphi_{\mathrm{par}} \rightarrow \varphi_{\mathrm{myo}}$

Several highly interesting and useful models of this so-called excitation–contraction coupling have been developed (see e.g. Hannaford (1990); Chou and Hannaford (1992); Otazu, Futami and Hoshimiya (2001); Wexler, Ding and Binder-Macleod (1997); Ding, Binder-MacLeod and Wexler (1998)), focusing on the different roles of the muscle proteins involved. The model presented here follows a recent approach by this author Nielsen (2006a); Nielsen (2006b) aimed at reducing the complexity and number of parameters of the previous models, in addition to provide a possible interpretation to the spike "doublets" often observed in spinal motor neurons (as defined in Simpson (1969), see also Maton and Bouisset (1975); Søgaard *et al.* (2001); Garland and Griffin (1999)). As described previously each muscle fiber is activated via an axon originating from a motor neuron in the spinal cord. The collection of all individual muscle fibers that a single motor neuron innervates is known as *motor unit*, a term coined by Sherrington in his early studies of the motor system (Sherrington, 1897). The ratio of innervation, that is the number of muscle fibers contacted by a single motor neuron, is highly correlated with the type of muscle fiber in question, so that strong fast fatigable fibers have very high innervation ratios, and the weaker and slow fatigue resistant fibers have very low innervation ratios (few fibers per motorneuron). This being so, one may wonder how precise control of muscle force is accomplished, and to this end there are several contributing factors. First, there are many more slow and weak motor units than fast and fatigable motor units. In fact, the actual number of motor units, n, producing a given force, ϕ, strongly depends on the force and roughly has the form $n(\phi) = \exp\{-\beta\phi\}$, where β is a scaling parameter that depends on the actual muscle in question, thus small and weak units are far more numerous than large and strong units (for more information regarding this distribution consult (Milner-Brown, Stein and Yemm, 1973)). Second, according to the Henneman size principle (Henneman, Somjen and Carpenter, 1965), motor units are recruited in order of increasing size, so the smallest units are recruited first, and the largest units last. This orderly recruitment leads to the observation that even when 50% of all motor units in the muscle have been recruited, only 20% of the total force is being produced (Walmsley, Hodgson and Burke, 1978), allowing for a very gradual increase in force.

Of course these facts have to be seen in proportion to the type of tasks that the skeletal musculature is usually requested to do. For example, one may calculate, that at 246.2 $\mathrm{km\,h^{-1}}$ it takes a tennis ball 346 ms to traverse the full length of a tennis court (record-breaking serve by Andy Roddick in 2004). Within this time, the opponent receiving the serve must judge the ball's trajectory, precisely move arm and racquet to a position where the serve may be countered and apply a controlled amount of force to return the ball and perhaps even score a point. Common values for reaction times to visual cues are in the order of 200 ms for simple behavioral responses like pressing buttons. More elaborate responses require more time. It is evident that precise voluntary movements require that muscles be rapidly brought from one predefined state of tension to another within precisely timed intervals. According to previously invoked size principle, slow and weak muscle fibers are recruited first, followed by strong, fast and fatigable fibers. Counting from the onset of a regularly firing spike train, it takes on the order of 20–100 ms for a relaxed fast muscle fiber to reach target tension. The corresponding figure for slow muscle fibers is about 300–1000 ms. This delay is not due to resiliency by the contractile machinery in the muscles, but is due to a relatively slow cumulative buildup of Ca^{2+} within the myoplasm following each spike. Thus, fast fibers might make it to the goal in time, but not so with slow fibers even if they are recruited first. In work by Nielsen (2006a); Nielsen (2006b) it is suggested, that in order to jump-start even slow (but strong) muscles, the nervous system might adopt a strategy where the insertion of spike "doublets" in an otherwise regular spike train will bring the muscle force up to a particular force level almost instantaneously (within milliseconds rather than the usually required hundreds of milliseconds), thus taking advantage of the so-called "catch-like" effect of skeletal muscle (first documented by Burke, Rudomin and Zajac (1970)).

9.6
Conclusion

It should be clear from the exposition above, that there is a very direct link between the action of specific proteins and the contraction of muscle. Simply put, proteins are required for every single step in the excitation–contraction coupling. However, it is only within the last decades where the tremendous advances in molecular biology and biophysics have allowed researchers to identify exactly which proteins are relevant and in which types of muscle, and to map out the intricate interaction networks between such proteins. Given the availability of such highly detailed interaction networks it is now feasible to routinely develop quite sophisticated network models accounting for different phenomena that one might observe in living muscle. Now comes the major task of putting in the right parameters, be they expressed as time constants, concentrations, coupling constants, rate constants, release fractions, force-extension profiles, and so on, that will make such models useful not only from a theoretical point of view, but also from the clinical perspective in order to start asking "what if" questions, and to develop novel approaches for improving or even repairing the body when it is broke. In the present exposition I have only tried to present some of the parameters that are usually considered important for understanding muscle function, focusing primarily on those parameters that have a direct link to protein action, and therefore no claims are made in favor of one or the other actual interaction model as this is considered outside the scope of this work. It is hoped that the reader will find inspiration in this work, perhaps as a stepping stone toward further exploration into the fascinating subject of muscle activation.

Fig. 9.2 Stretching experiment performed *in silico* using steered molecular dynamics in order to apply controlled forces on different parts of a myosin molecule. (a) The myosin molecule was stretched out to a predetermined extension and then held at that position to sample the reactive force produced by the molecule. The colored blobs indicate force-extension samples resulting from five different stretch–hold experiments. A line fitting these samples is shown together with a family of dashed lines corresponding to best fits using the worm like chain model expressed by Eq. (3) and using persistence lengths from 2 to 5 Å, and contour lengths of 20–40 nm (explanation in text). (b) The molecule was continuously stretched at a high velocity and the reactive force was plotted. The best fit worm like chain model is also shown as a black line. In both cases coordinate data corresponding to scallop myosin in near rigor state was obtained from the Protein Data Bank (pdb-id: 1SR6), from which a sub region was selected to represent the neck region of the molecule, corresponding to residues 473–584, 693–728, and 738–781, and shown in the figure as the first molecular structures surrounding the plots (upper left structure). This subregion was equilibrated using molecular dynamics (NAMD2 developed by Kalé *et al* (1999), and a number of α carbon atoms was fixed while the α carbon of residue 774 was pulled in different directions depending on the case, either as a stretch–hold experiment (a) or constant velocity pulling experiment (b), resulting in the other molecular structures shown. (This figure also appears on page 316-317.)

10.1
Introduction

The canonical picture of a biological membrane is that of an amphiphatic barrier to polar solvents defining enclosed cellular and subcellular spaces. Its fundamental constituents are lipid-class molecules, specifically phospholipids arranged in a double layer – a lipid bilayer, and a variety of proteins involved in transport of material and material across the membrane. The cohabitation of proteins and lipids naturally leads to the question of how the two species mutually interact.

Historically, the picture of biological membranes has emerged over the last century and a half, starting in 1855, with the observation of Swiss botanist Nägeli and his student Cramers of the different rates of pigment penetration into damaged and undamaged plant cells (Nägeli and Cramer, 1855). Their conclusion was that plant cells contain an outer layer which was coined the *plasma membrane*. Later, in 1877, Pfeffer devised a permeable membrane for the study of osmosis, and the mathematical relationship to predict osmotic pressure was developed by Jacobus van't Hoff (Andrews, 1929). Pfeffer concluded that the membrane essentially was a permeability barrier to water and polar solutes. This view was modified by Overton who concluded that the entry of any molecule into a cell is the result of its "selective solubility" in the cell's boundary, and that the more soluble in lipids the molecule is, the greater is its permeability – now known as *Overtons Rule* (Overton, 1899).

Thanks to the work of the French chemist Chevreul in the early 1800s, the chemical and physical nature of lipids and fatty acids was understood reasonably well (Chevreul, 1889; McNamara, Warnick and Cooper, 2006). Overton further suggested that the cell membrane contained cholesterol and lecithins (generally denominating a mixture of glycolipids, triglycerides, and phospholipids, but biochemically used as synonym for phosphatidylcholine) (Overton, 1899). Although later studies, including Walther Nernst's formal introduction of the semi-permeable membrane concept in 1908 (Nernst, 1909), refined the conceptual framework, and confirmed Overton's findings, membrane structure remained highly controversial. An important observation, made in 1917 by Langmuir, was that lipid molecules spread out into a one-molecule thick layer at air–aqueous buffer interfaces (Langmuir, 1917). This finding was

complemented in 1925 by Gorter and Grendel leading to the bilayer model of the plasma membrane (Gorter and Grendel, 1925). About 10 years later Danielli, working with Harvey, observed that proteins could bind to mackerel oil, and in 1935, together with Davson, Danielli proposed a biological membrane model consisting of a lipid bilayer sandwich covered with proteins on both sides facing the aqueous phases (Danielli and Davson, 1935). With the advent of electron microscopy in the 1950s, Robertson was able to resolve a trilaminar structure and he interpreted this as reflecting two protein coats encapsulating the lipid bilayer and coined the term *unit membrane* for this arrangement (Robertson, 1966). Around the same time, the globular structure of soluble proteins was recognized and generally attributed to the spherical arrangement with the hydrophobic part shielded from the aqueous solvent. This prompted (Lenard and Singer, 1966), and (Wallach and Zahler, 1966) independently to propose a different model for the arrangement of proteins and lipids in biological membranes. Owing to the hydrophobic interior of the lipid bilayer, proteins could in fact be globular entities penetrating into and sometimes spanning the hydrophobic thickness of the lipid bilayer, provided that these proteins adopted conformations that would allow this arrangement. Singer later elaborated the thermodynamic basis for membrane-associated proteins having distinct hydrophobic regions that would be shielded from the aqueous phase by inserting themselves into the bilayer hydrophobic core (Singer, 1971).

In 1971, at a meeting at the New York Academy of Sciences (Green, 1972), a final consensus emerged that biological membranes are liquid-crystalline bilayers. This was summarized in the notorious *fluid-mosaic* Singer–Nicolson model (Singer and Nicolson, 1972). In this model, the outer surfaces are composed primarily of charged and polar lipid head groups and interact with the aqueous phases, whereas the inner portion of the bilayer is composed of the hydrocarbon chains of the lipids aligned parallel to each other, having some flexibility allowing for methylene group rotamatic states. The nonpolar acyl chains are in contact with each other at the terminal methyl group, and this arrangement creates a hydrophobic barrier impermeable to polar solvents, for example, ions, but allow small nonpolar molecules to pass, for example, ethanol and diatomic neutral gasses. Although the original model has been extended and refined to include nonhomogeneous distribution of lipid components, glycocalyx, and cytoskeletal elements (Sackmann, 1984; Mouritsen and Andersen, 1998), its prime conceptual feature is that the membrane is a dynamic (fluid) matrix in which the proteins and lipids can move and interact.

The permeability of pure lipid bilayers is consistent with the approximation that lipid bilayers essentially are 5-nm thick two-dimensional sheets of liquid hydrocarbon (Fettiplace and Haydon, 1980). This suggests that the Singer–Nicolson model implies an impermeable lipid matrix acting as a passive, albeit, fluid solvent for embedded proteins, but this view does not provide a viable basis for understanding the increasing evidence for specific and unspecific, and, to some extent, reciprocal interactions between the lipid bilayer and membrane proteins (Andersen, Sawyer and Koeppe, 1992).

In the following, we limit the scope to integral membrane proteins and focus on their interaction with the host lipid bilayer. First, the general structure, the lipid bilayer, and transmembrane-spanning protein structure is presented. Second, some examples of how spectroscopic techniques can be used to understand protein conformational structure in lipid bilayers are discussed. Finally, the concept of elastic membrane deformations is presented and implications of deformation free energies for protein function are discussed.

10.2
Hydrophobic Matching Principle

The permeability barrier properties of biological membranes entail that membrane proteins are inserted into the lipid bilayer without compromising these properties and/or compromising protein function and stability. The evolutionary consequence of this is that membrane and membrane proteins must have coevolved. The structural consequence is that proteins and lipids must be compatible in the sense that transmembrane-spanning proteins must contain regions that are sufficiently “lipid-like” to match the surrounding membrane constituents (see Figure 10.1). This is expressed in the notion of hydrophobic matching arising from the hydrophobic effect. For an acyl chain, each CH_2 group adds 0.8 kT of energy (Cevc and Marsh, 1987), and it would require >100 kT to expose a membrane edge with the size corresponding to an integral membrane protein to water (Sharp *et al.*, 1991). Thus understanding the mutual lipid–protein matching ability requires an understanding of both bilayer and protein structure.

10.3
The Lipid–Protein Matrix

Both lipids and membrane-spanning proteins have proven to be elusive entities in the sense that it is difficult to obtain structural information. Lipids are generally in the fluid state rendering it difficult to construct structural models. Membrane proteins are notoriously difficult to crystallize and obtain structural information from despite very impressive

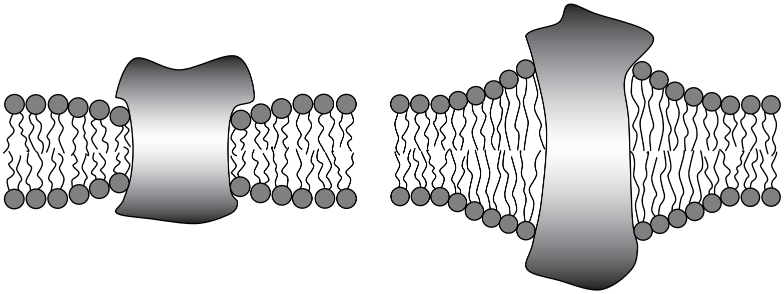

Fig. 10.1 The hydrophobic matching (Mouritsen and Bloom, 1984) implies that whenever the hydrophobic length of an integral membrane-spanning protein is different from the hydrophobic thickness of the unperturbed bilayer, there will be a bilayer deformation involving bending and compression (a) or expansion (b) of the bilayer.

progress made over the last decade, for example, Doyle *et al.* (1998); Jiang *et al.* (2003); Toyoshima *et al.* (2000); Morth *et al.* (2007). Moreover, the intricate interplay between a large number of various proteins, lipids, and cytoskeletal elements remains the major obstacle in a detailed functional understanding of all elements of the biological membrane.

In energetic terms, the understanding of lipid–protein interplay translates into quantifying the plethora of component energies for the various interactions between the elements of the membrane. One of these component energies constituting the total free energy associated with two different conformations of a bilayer embedded protein is based on the reciprocal coupling between lipid and protein arising from the hydrophobic matching principle. In this way, the hydrophobic matching leads to a reciprocal hydrophobic coupling between bilayer (structural and mechanical) properties and protein structure and function (Mouritsen and Bloom, 1984; Andersen and Koeppe, 2007). To assess the energetics of this hydrophobic coupling, structural information about both lipids and proteins is necessary.

10.3.1
Biological Membranes

Despite the apparent simplicity of the Singer–Nicolson model for lipid bilayers, progress in understanding the molecular structure of biological membranes has been hampered by the complex lipid biochemistry. A typical biological membrane contains hundreds of chemically distinct lipids with great variation in the structures of the acyl chains and lipid headgroups (Dowhan, 1997). In addition, there is substantial variability in composition across cell types. Evidently, the cellular requirements for lipid-based chemical signaling constitute a major reason for this complexity, but still it is not generally clear how the lipid composition for a membrane is maintained (Hazel, 1995) and what an acceptable/optimal composition is, for its embedded proteins to function.

10.3.1.1 Properties of Fluid Lipid Bilayers

Although diffraction studies of phospholipid crystals (i.e. below the main gel-to-liquid transition temperature T_m) at low hydration can provide detailed images in which the mean relative positions are well defined and measurable (Pascher *et al.*, 1992), this is not possible for fluid lipid bilayers (i.e. above T_m) where the acyl chains have considerable flexibility with varying torsion angles (the most stable being *trans* (180°) and *gauche* (60°)) along the acyl chain. Instead, one must consider the average spatial distributions of lipid molecule moieties. Thus, one can obtain a bilayer profile in which the various components (e.g. phosphate and choline groups and the methylene region) can be identified as peaks at various positions from the bilayer midplane. White and colleagues have combined X-ray and neutron-diffraction data using joint-refinement procedures (Wiener and White, 1991a, 1991b) and provided multi-Gaussian distribution quasi-molecular models of hydrated (66% relative humidity) dioleoylphosphatidylcholine ((diC18:1)PC) (Wiener, King and White, 1991; Wiener and White 1992a, 1992b). The interfacial regions appear fuzzy in these models. Nevertheless, the bilayer *equilibrium* thickness d_0 can be regarded as a well-defined entity.

Using deuterium quadrupole coupling nuclear magnetic resonance (NMR) an order parameter describing the disorder arising from thermal motion of the acyl chains can be obtained for fluid liquid-crystalline bilayers (Seelig and Seelig, 1974; Seelig, 1977). The order parameter displays a plateau for acyl chain carbons 2–8, whereas segments 10–16 (in the case of dipalmitoylphosphatidylcholine (DPPC)) show increased frequency of rotational isomerization toward the terminal methyl group. The order parameter value for the plateau is quite low with 60% disorder. Interestingly, the order parameter plateau length for DPPC is mirrored in the structure of biological membranes. Prokaryote lipids are typically monounsaturated with the double bond between carbon 9 and 10 (Kenyon, 1978). Eukaryote lipids contain sterols where the rigid polycyclic sterol ring system lies in the membrane between carbon 2 and 9 with its flexible side chain resting between carbon 10 and the terminal end of the acyl chains (Engelman and Rothman, 1972).

The T_m for a series of monounsaturated dioctadec-*cis*-enoyl phosphatidylcholines into which the single *cis*-double bond was inserted at positions 2–17 displays a minimum with the double bond at position 9 (Barton and Gunstone, 1975). Although this observation could lead to the conclusion that the double bond at position 9 serves to increase the "fluidity" of the bilayer, this is not the case. T_m gives information about the stability of the gel state, not the fluid state. Fluidity (i.e. the inverse of viscosity) above T_m, is not affected by the position of the double bond.

Even though the (fluid) liquid-crystalline organization of the lipid bilayer is necessary to allow for conformational changes involving the protein–lipid boundary, the focus on membrane fluidity as *the* determinant for membrane function as it has developed over the last three decades is problematic. First, the term itself is not a well-defined experimental entity. Fluidity is proportional to the rate of motion, but the behavior of many probes with which fluidity has been measured is sensitive to both rate and range of probe motion. Second, important in the context of lipid–protein interactions, it has been pointed out by Lee (1991) that changes in fluidity itself cannot affect the conformational equilibrium between interconverting membrane protein conformations – it only affect the kinetics. Thus the equilibrium distribution among protein conformational states is not affected by changes in fluidity. To understand how the membrane may affect protein function, one therefore has to focus on the energetic modulation of protein conformational equilibrium by the host membrane (Andersen and Koeppe, 2007).

10.3.1.2 **Mechanical Properties of Lipid Bilayers**

The energetics of bilayers is closely linked to their mechanical properties. In this respect, it is useful to treat the bilayer as a continuum entity with physical–chemical properties (Zimmerberg and Gawrisch, 2006). The theoretical description of elastic membrane deformations has evolved greatly since the seminal contribution from Helfrich (1973). In this description, the bilayer material properties are defined by the hydrophobic bilayer thickness d_0, the intrinsic lipid curvature (or monolayer equilibrium curvature) c_0, and the elastic moduli for bilayer compression – expansion K_a and bending K_c. The thickness d_0 of a fully hydrated saturated phosphatidylcholine in the liquid-crystalline state lipids is related to acyl chain length through the semi-empirical approximation:

$$d_0 = 1.75(n-1) \tag{1}$$

where n is the number of acyl chain carbon atoms (Lewis and Engelman, 1983; Sperotto and Mouritsen, 1988). Introducing two monounsaturated acyl chains lowers d by approximately 2.5 Å. As an example, according to Eq. (1), a distearoylphosphatidylcholine (di(C18:0)PC) bilayer has thickness of 29.7 Å, whereas ((diC18:1)PC) has a thickness of 27.2 Å, the latter value in agreement with 27.1 Å from refined diffraction measurements (Nagle and Tristram-Nagle, 2000). A lipid bilayer made from 1-stearoyl-2-oleoyl-phosphatidylcholine (C18:0–C18:1PC), a lipid that can be seen as a representative for a typical plasma membrane lipid, has a thickness of 30.7 Å (Rawicz *et al.*, 2000). Measurements of bilayer electrical capacitance can also provide information about d_0 as the specific capacitance $C_m = \varepsilon\varepsilon_0/d_0$ where ε is the dielectic constant corresponding to a long hydrocarbon ($\varepsilon = 2.1$ for hydrocarbons (Fettiplace, Andrews and Haydon, 1971) and increases by approximately 0.2 per double bond (Lide, 1996)), and $\varepsilon_0 = 8.85 \cdot \times 10^{-12}$ F m^{-1} is the permittivity of free space. This has been investigated in bilayers formed from natural and synthetic lipids dissolved in different n-alkanes (Andrews and Haydon, 1968; Läuger *et al.*, 1967; White and Thompson, 1973), a system often used in protein reconstitution experiments, for example Green, Weiss and Andersen, (1987). By measuring C_m the bilayer thickness was found to decrease with increasing alkane length. For (diC18:1)PC, $d_0 = 49.3$ Å with n-octane as solvent $d_0 = 29.8$ Å with n-hexadecane as solvent (Benz and Janko, 1976). For nominally solvent free membranes formed by the folding of two spread monolayers (Montal and Mueller, 1972; Bamberg and Benz, 1976), $d_0 = 25.8$ Å for(diC18:1)PC is in good agreement with the diffraction data mentioned above.

In general, literature values for lipid bilayer structure (e.g. thickness and area per lipid headgroup) show significant variation, partly due uncertainties in hydration level (Rand and Parsegian, 1989), but recent progress has reduced this problem producing values for fully hydrated liquid-crystalline lipid bilayers (Nagle and Tristram-Nagle, 2000; Katsaras, 1997, 1998).

As d_0 is orders of magnitude smaller than the lateral micrometer extent of biological lipid bilayers, membrane mechanical properties can be approximated to those of a thin deformable sheet. In general, a sheet can be deformed in three principal ways: stretching, bending, and shearing. While fluid lipid bilayers have no resistance to shear (Evans and Skalak, 1980), compression–expansion (CE) and bending or splay-distortion (SD) can be quantified in terms of energy per unit area as

$$E_{\mathrm{CE}} = \frac{1}{2} K_{\mathrm{A}} \left(\frac{u}{d_0}\right)^2 \tag{2}$$

where u is the thickness change from equilibrium thickness d_0, and

$$E_{\mathrm{CE}} = \frac{1}{2} K_{\mathrm{C}} \left[\left(\frac{1}{R_1} + \frac{1}{R_2}\right)^2 - \frac{1}{R_0^2}\right] \tag{3}$$

where R_1 and R_2 are the principal radii of curvatures and $R_0 = 1/c_0$ the equilibrium curvature radius). In a sheet (shell) description of the bilayer (Evans and Skalak, 1980), K_A and K_C are related to each other via d_0:

$$K_{\mathrm{C}} = d_0^2 K_{\mathrm{A}} \tag{4}$$

In addition, there is a surface energy term due to changes in bilayer surface area ΔA relative to the equilibrium area A_0 upon bending with a characteristic interfacial tension Γ

$$E_{\mathrm{ST}} = \Gamma \left[\left(\frac{\partial u}{\partial x} \right)^2 + \left(\frac{\partial u}{\partial y} \right)^2 \right] \tag{5}$$

Bending and curvature are related through the lateral stress profile as a function of distance normal to the bilayer surface for the monolayer $t(z)$. The lateral stress profile is a result of intermolecular interactions within the bilayer, which leads to positive and negative lateral pressures in a direction parallel to the bilayer surface (Cantor, 1997a,b, 1999). In the headgroup region, these interactions include steric, hydrational, and electrostatic repulsion (Seddon and Templer, 1993). In the two interfaces between polar and nonpolar regions, there is an attractive lateral tension as a result of the hydrophobic effect attempting to minimize water contact with the hydrophobic core region. Finally, in the core acyl chain region, interactions include van der Waaals attractive forces, as well as repulsive forces exerted by thermally activated *trans–gauche* rotameric states of the acyl chains. For a monolayer in equilibrium, the net tension is zero, which corresponds to

$$\int_{\text{Monolayer total thickness}} t(z)dz = 0 \tag{6}$$

The torque acting on the monolayer is given by the first moment of $t(z)$:

$$\int_{\text{Monolayer total thickness}} zt(z)dz = -K_c c_0 \tag{7}$$

Thus, whenever $c_0 \neq 0$ there will be a net torque on the monolayer acting relative to the neutral surface (the surface of inextension during pure bending), which will force the monolayer to curve away from or toward the aqueous phase. This corresponds to an imbalance of forces making up $t(z)$. For a bilayer made of two opposing monolayers each with $c_0 \neq 0$ this will result in a frustrated bilayer in which energy is stored.

The lateral stress profile is often described in simple geometric terms leading to the concept of effective lipid molecule shape (Luzzati and Husson, 1962; Israelachvili, Marcelja and Horn, 1980; Israelachvili, Mitchell and Ninham, 1976; Israelachvilli, 1992) (see Figure 10.2). Thus lipids can be described as having an effective cylindrical shape when the torque is zero ($c_0 = 0$), and these lipids form relaxed bilayers. When the effective cross-sectional area of the headgroup region is larger than that of the acyl chain region, the monolayer has a $c_0 > 0$. The result is effectively cone-shaped lipids forming a convex surface when viewed from the aqueous phase. Conversely, when the effective cross-sectional area of the headgroup region is smaller than that of the acyl chain region, the monolayer has a $c_0 < 0$. This results in effectively inverted cone-shaped lipids forming a concave surface when viewed from the aqueous phase. In a bilayer, the two monolayers are coupled in the sense that they must have complementary curvatures.

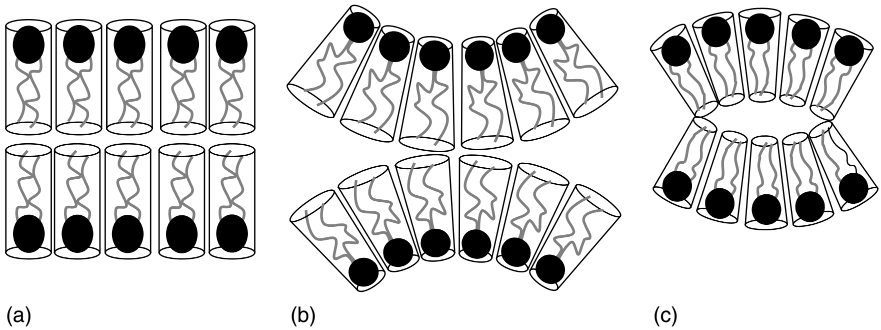

Fig. 10.2 The effective shape concept for lipid molecule geometry. Effectively, cylindrically shaped lipid molecules self-assemble into in stress-free bilayers (a) Whenever the effective shape is noncylindrical, the monolayers will have a propensity to form curved interfaces with $c_0 < 0$ (b) or $c_0 > 0$ (c). Forcing two opposed curving monolayers into a bilayer will result in a curvature-stressed or frustrated bilayer in which energy is stored.

Hence, the monolayer equilibrium curvature is determined by the effective molecular shape, whereas the coupling between monolayers determines the bilayer curvature.

The effective shape image of lipid molecules has been very useful in predicting pure lipid phases (Seddon, 1990; Cullis and deKruijff, 1979) and "curvature-stress" has been described as a major (if not the most important) regulating factor for membrane protein regulation (Gruner, 1985; Stubbs and Slater 1996; Ces and Mulet, 2006). It is, however, important to underline that curvature-stress (given by the "effective values" of K_c and c_0) constitutes only part of the description of mechanical properties of bilayers. Also, assigning shapes is, in fact, a retrospective operation, in the sense that shape and c_0 are based on structural data on spontaneous (macroscopic) phases. Although one may intuitively predict curved phases from say lysophospholipids (Lundbæk and Andersen, 1994), it is not straightforward to generalize the effects of, say, polyunsaturated fatty acids (PUFAs) on membrane properties based on their apparent molecular shape only (Bruno, Koeppe and Andersen, 2007) despite progress in predicting lipid effective structures (and phases) from microscopic models (Li and Schick, 2000).

10.3.2
Transmembrane Spanning Proteins

Integral (bitopic or multitopic) membrane proteins contain one or more regions that allow them to insert partially into, or fully traverse the hydrophobic core of the lipid bilayer. The association with the lipid bilayer implies that detergents or some other nonpolar solvents are required to dissociate them from the lipid matrix cf. (Ollivon *et al.*, 2000). Both classes can be post-translationally modified with added fatty acid chains (acylated), prenyl chains (prenylated), or glycosylphosphatidylinositol (GPI), where these additions serve as to anchor the protein in the lipid bilayer (Resh, 2006; Paulick and Bertozzi, 2008).

10.3.2.1 General Energetic Considerations

For all structures of membrane-spanning peptide chains known to date, the condition of complete satisfied hydrogen bonds is satisfied. The reason for this lies in the fact than an unsatisfied hydrogen bond in a hydrophobic environment is energetically unfavorable. The difference in free energy change for transferring of peptide bonds, with and without hydrogen bonds, amounts to 6.7 kT (Roseman, 1988). For a 20-amino acid segment, this corresponds to 133 kT, which prohibits insertion of nonstructured (nonhydrogen bonded) segments into the membrane. All known integral membrane protein structures traverse the membrane with either α-helices or β-strands producing helical bundle proteins or β-barrel proteins.

10.3.2.2 Helical Bundles

In the case of an α-helical structure with bacteriorhodopsin as the canonical example, the amino acids are arranged in a right-handed structure (favored by steric constraints given by the fact that as all amino acids except glycine have the l-configuration). As each amino acid corresponds to a 100° turn in the helix, the helix has 3.6 residues per turn, corresponding to a shift of 1.5 Å along the helical axis. The N—H group of an amino acid forms a hydrogen bond with the C=O group of the amino acid four residues earlier; this repeated hydrogen bonding pattern defines an α-helix (Pauling, Corey and Branson, 1951). The α-helix is packed with vanishingly little free space within the helix. The amino acid side chains are all on the outside of the helix and oriented toward the *N*-terminus.

How do helix–helix interactions affect the structural arrangement of transmembrane-helical proteins? The recent development of simple transmembrane helical bundle model systems opens possibilities for a quantitative understanding, and several groups have studied these systems. For example, the dimerization of GpA – a small erythrocyte transmembrane protein – has been extensively studied in bilayers, native membranes, and detergent micelles (for a review see Lemmon and Engelman, 1994). Site-directed mutagenesis has revealed an association motif LIXXGVXXGVXXT where X represents any amino acid (Lemmon *et al.*, 1992; Mingarro *et al.*, 1996). Using solid states NMR, the crossing angle between the two monomers of GpA in dodecyl phosphatidylcholine bilayers was found to be 25°. This is in agreement with modeling studies (Treutlein *et al.*, 1992) showing that the two glycines from each monomer line the dimer interface allowing the two helical polar backbones to bind tightly. The valine, leucine, and threonine residues in the motif further extend the interface, and when the helices are docked for maximal interaction they form an interhelical angle of 30–40°.

10.3.2.3 β-Barrels

For β-barrel proteins (e.g. bacterial porins), the secondary and tertiary structure is closely linked as the protein contains β-strands that twist to form a closed structure in which the first strand is hydrogen bonded to the last. The strands are generally arranged in an antiparallel arrangement so that the *N*-terminus of one strand is adjacent to the *C*-terminus of the next. This structure has a high stability because it allows the interstrand hydrogen bonds between carbonyls and amines to be in their preferred planar orientation.

β-Barrels can be classified in terms of two parameters: the number of strands in the β-sheet, n, and the so-called shear number, S, a measure of the stagger of the strands in the β-sheet (Liu, 1998; McLachlan, 1979). n and S are related to the inclination-angle of the β-strands relative to the axis of the barrel. The stagger (or strand tilt) originates in the chirality of the amino acids in the strand. This implies that even though only 7 amino acid residues are needed to span the membrane, typical transmembrane β-strands have 9–11 residues giving a strand tilt between 20° and 45°. The result is a circular pattern where none of the strands are left without a partner. For an eight-strand β-barrel protein, breaking all hydrogen bonds in the bilayer environment would cost 536 kT (8 strands with 10 bonds per strand times 6.7 kT per bond). With the number of strands varying from 8 to 22 implies that β-barrels are extremely stable in an bilayer environment.

10.3.2.4 Interfacial Anchoring of Transmembrane Segments

A ubiquitous feature of both α-helical and β-barrel membrane-spanning proteins seems to be a preference of tryptophan (W) and tyrosine (Y) residues at the interfacial lipid headgroup region (Schiffer, Chang and Stevens, 1992). Statistical analysis of membrane protein sequences indicates that this preference is a general feature (Landolt-Marticorena *et al.*, 1993; von Heijne, 1994). The preference has been discussed in terms of so-called anchoring by flanking residues in the sense that the aromatic or charged residues serve as to symmetrically anchor membrane-spanning proteins at the interfacial regions in the membrane (Schiffer, Chang and Stevens, 1992; Killian and Heijne, 2000; de Planque and Killian, 2003; Reithmeier, 1995). Studies with small membrane-adsorbed model peptides and model transmembrane helical proteins suggest that the preference for aromatic residues at the interface is related to distinct interfacial interactions (Jacobs and White, 1989; Wimley and White, 1996; Kachel, Asuncion-Punzalan and London, 1995; Morein *et al.*, 1997; Yau *et al.*, 1998) including electrostatic and cation–π interactions (Gaede, Yau and Gawrisch, 2005; Petersen, Jensen and Nielsen, 2005).

10.3.2.5 Proteins as Embedded Inclusions

Since the volumetric compressibility moduli for globular proteins in aqueous solution is about $10^{10} - 10^{11}$ N m^{-2} (Gekko and Noguchi, 1979) compared to 10^9 N m^{-2} for liquid-crystalline bilayers (Liu and Kay, 1977) and 10^8 N m^{-1} for bilayer thickness compressibility (Evans and Hochmuth, 1978), both α-helical and β-barrel proteins essentially are rigid structures embedded in a soft fluid membrane. Owing to the architecture of β-barrels, it is not likely that their function involve extensive conformational changes. On the other hand, the function of α-helical proteins typically depends on reorganization of the structure, that is they can convert (discretely or gradually) between various conformational states where the free energy for conformational transitions not only comes from the protein (e.g. helix–helix interactions) but also from "external" sources. One of the sources contributing to the free energy associated with conformational transitions or helical tilting is the membrane environment (Andersen and Koeppe, 2007) because proteins are hydrophobically coupled to the membrane and also in several cases anchored by interfacial aromatic residues. In this regard, single transmembrane-spanning α-helical proteins/peptides constitute a special group of inclusions in the sense that they have the smallest possible hydrophobic inclusion volume and are therefore likely to respond to changes in bilayer properties in ways not possible for larger (helical bundle/barrel) proteins by, for example, tilting the entire protein relative to the bilayer normal or by allowing formation of kinks in the helix. This raises the question as how to assess protein structure (i.e. conformation and helical tilt) *in situ* in the fluid bilayer.

10.4
Determining Membrane-Spanning Protein Structure and Orientation in Fluid Lipid Bilayers

Many techniques including X-ray crystallography, fluorescence resonance energy transfer (FRET), and quenching can be used to study lipid–protein interactions. Fluorescence techniques are especially relevant in studies of partition of peptides into membranes, protein/peptide aggregation, and lipid selectivity (Reyes Mateo *et al.*, 2006). X-ray is a powerful structural technique for membrane proteins *per se* but in the context of lipid–protein interactions it literally provides a frozen picture at low temperature and thus providing information about a membrane environment very different from that of a fluid liquid-crystalline bilayer (Lee, 2005). In the study of integral membrane protein structure and orientation in fluid bilayers, two classes of techniques are especially valuable: NMR-based techniques and electron paramagnetic resonance (EPR) (also referred to as electron spin resonance (ESR)) techniques.

10.4.1
Some Insights from Nuclear Magnetic Resonance (NMR) Spectroscopy

Structural determination using NMR has previously been limited to small proteins. However, the development of sophisticated methods such as transverse relaxation optimized spectroscopy (TROSY) and solution NMR has provided complete structures of bacterial β-barrel proteins such as OmpX, OmpA, and PagP reconstituted in micelles (Fernandez *et al.*, 2004; Arora *et al.*, 2001; Hwang *et al.*, 2002).

Recent developments in aligned-sample solid-state NMR techniques have allowed for detailed information about transmembrane protein conformation. By combining chemical shift and spin–spin coupling, it is possible to obtain detailed information about the orientation of transmembrane α-helices and β-barrels in fluid bilayers (Marassi and Opella, 2000; Gong, Choi and Marassi, 2006; Wang *et al.*, 2000). In order to appreciate this technique, it is to be noted that the angular dependence of the dipolar coupling D is given as $D(\theta) \propto 3\cos^2\theta - 1$, which implies that $D = 0$ at the so-called magic angle: $\theta = \arccos 1/\sqrt{3}$ where the effect of magnetic susceptibility is also minimal. Spinning the samples at the magic angle relative to the $\mathbf{B}$ field has, for example, been a successful tool in determining lipid structure from ^{2}H spectra (Herzfeld *et al.*, 1980; Yeagle and Frye, 1987; Oldfield, Bowers and Forbes, 1987). The principle in magic angle spinning (MAS) has been further developed and is now used in characterization of lipid–protein interactions.

Using a phase and frequency-shifted pulse sequence for the **B** field, it is possible to lock all the ^{1}H spins at the magic angle so that their dipole coupling goes to zero. Simultaneously, another set of synchronous pulses in antiphase allows the ^{15}N nuclei to exchange spin with the ^{1}H nuclei. When this spin exchange has stopped, the ^{15}N magnetizations that are modulated by what happened during spin exchange can be recorded. Fourier transforming from the time to the frequency domain yields a two-dimensional spectrum. This is the so-called polarization inversion with spin exchange at the magic angle (PISEMA) (Wu, Ramamoorthy and Opella, 1994). A two-dimensional ^{1}H-^{15}H dipolar coupling/^{15}N chemical shift PISEMA resonance spectrum displays a characteristic structure referred to as a *polar index slant angle* (*PISA*) diagram (Marassi and Opella, 2000). For an α-helical protein, each point in the wheel-like diagram corresponds to the NH half of each peptide bond (H-bonded to the CO of a peptide four bonds away in the chain) whose ^{15}N chemical shift and ^{1}H $-^{15}$H dipolar coupling both depend on the orientation of the bond with respect to the **B** field. As a result, the shape and position of the PISA wheel is a direct measure of helical orientation (or tilt) in the membrane.

Spectral calculations based on an ideal immobile α-helix or β-strand with uniform dihedral angles and with the helix/strand long axis making a fixed angle with the external **B** field yield precise theoretical PISA diagrams (Gong, Choi and Marassi, 2006), but predicting them from crystallographic data is not straightforward due to the relatively low structural resolution and the high sensitivity of the wheels to local structural variations (shielding variation). This, combined with the fact that membrane proteins are dynamic entities, has led to doubts whether PISA spectra would be generally observed in membrane proteins (Straus, Scott and Watts, 2003). There are now 10 structures in the Protein Data Bank characterized by aligned-sample solid-state NMR techniques (Li *et al.*, 2007), and recent advances in probe technology (Gor'kov *et al.*, 2007) and sample preparation have made it possible to obtain spectra of fully aligned full-length proteins confirming the existence of measurable PISA spectra in membrane proteins.

The use of model peptides in NMR studies has also revealed how isolated membrane-spanning segments orient themselves in lipid bilayer and, in particular, how they respond to changes in the hydrophobic thickness of the bilayer. Specifically, studies of model peptides based on a Acetyl-GW$_2$(LA)$_n$W$_2$A-amide (WALP) and Acetyl-GK$_2$(LA)$_n$K$_2$A-amide (KALP) peptides have provided valuable information (for recent reviews see (de Planque and Killian 2003; Killian and Nyholm, 2006)). For example, insight into the possible role of anchoring residues was obtained by de Planque *et al.* using ^{31}P and ^{2}H NMR (de Planque *et al.*, 1999) who found that W-residues anchor at the interface, whereas K-residues preferentially positions its positively charged amino group close to the lipid phosphate groups. The length of K-flanked peptides can be effectively modulated by "snorkeling," that is stretching of the charged group toward the aqueous phase (de Planque *et al.*, 1999; Strandberg *et al.*, 2002), whereas W-residues resist displacement of their preferred interfacial localization upon a hydrophobic mismatch challenge (de Planque *et al.*, 2003) pointing to the role of W-residues in protein anchoring. ^{15}N NMR studies on lysine (K)-flanked model peptides suggest a considerable tilt (Harzer and Bechinger, 2000) when inserted in a bilayer with a smaller hydrophobic thickness compared to the hydrophobic length of the peptide. Also the *N*-terminal channel forming domain of the membrane protein VpU from HIV-1 showed tilt angles sufficient to compensate for mismatch. In contrast, ^{2}H NMR studies of WALP and KALP only showed a small response to a similar hydrophobic mismatch (Strandberg *et al.*, 2004; Ozdirekcan *et al.*, 2005), although very long WALPs and KALPs adopt helical structures with a central kink in thin lipid bilayers (Daily *et al.*, 2008). Whether this discrepancy is due to differences in experimental parameters or intrinsic peptide properties (e.g. side chain chirality and/or the unnatural poly(AL) sequence in WALP/KALP) still remains an open question.

10.4.2
Some Insights from Electron Paramagnetic Resonance (EPR) Spectroscopy

For more than 30 years, EPR has been used in the studies of lipid organization (Lee, 2005). In these studies, nitroxide spin labels are attached to selected positions in the acyl chains. One of the major results is the detection of so-called boundary or annular lipids, a subpopulation of highly immobilized lipids seen in lipid–protein preparation but not in pure lipid systems (Jost *et al.*, 1973; Jost and Griffith, 1978; Brotherus *et al.*, 1981). The number of annular lipids, that is, the number of lipids that bind to the hydrophobic exterior of a membrane protein, can be quantified (Jost and Griffith, 1978; Brotherus *et al.*, 1981), and the number fits well from estimates based on average area per lipid and protein circumference (Marsh and Horvath, 1998; Marsh and Pali, 2004). However, due to the ESR timescale of 10^{-8} seconds, identification and quantification of annular lipids must be performed at low temperatures (Lee, 2005). At higher temperatures rates for lipid molecule movement in and out of the annular region (described by on and off rate constants) can be detected. The on rate is diffusion controlled, whereas the off rate reflects any specificity in binding (Marsh and Horvath, 1998; East, Melville and Lee, 1985; Davoust and Devaux, 1982). At 30 °C, off rates are about $1–2{\cdot}10^{7}\ s^{-1}$ and this is somewhat lower than the diffusional exchange of $8 \cdot 10^{7}\ s^{-1}$ in the bulk membrane. However, combined with results from fluorescence quenching (East and Lee, 1982), it appears that apart from specific hotspots with selectivity for anionic lipids the lipid–protein interaction, nevertheless, is rather nonspecific (Lee, 2005).

Recent developments in EPR techniques have opened up for investigations of helical peptides incorporated in aligned bicelles (discoid bilayers) (Inbaraj *et al.*, 2006), nanotube arrays (Karp *et al.*, 2006), and bilayers (Inbaraj, Laryukhin and Lorigan, 2007; Mayo *et al.*, 2008). Using the tetra-substituted unnatural amino acid, 2,2,6,6-tetramethyl piperidine 1-oxyl-4-amino-4-carboxylic acid (TOAC) that exhibits highly restricted motion (Inbaraj *et al.*, 2006) attached to the backbone of a transmembrane, helix information about helix tilt angle can be obtained quite accurately (Inbaraj *et al.*, 2006). This method can be applied for peptides and small proteins (<60 amino acids) and appears superior to approaches using standard cystein-bound 1-oxyl-2,2,5,5-tetramethyl-d3-pyrroline-3-methylme-thane-thiosulfonate spin label (MTSSL) in which there are several flexible bonds between the helical peptide backbone and the nitroxide group. Also, introducing the TOAC label in membrane proteins does not alter secondary structure (Karim *et al.*, 2004).

Using the 23-amino acid, long M2δ domain of the nicotinic acetylcholine receptor (AchR) ion channel as a model for a transmembrane helical segment, the tilting value could be compared with known helical tilt information based on the PISEMA approach mentioned in Section 4.1. The M2δ segment was found to tilt 14° with respect to the bilayer normal both in bicelles and bilayers, consistent with NMR data (Inbaraj *et al.*, 2006). The advantage of the TOAC EPR approach is that it is orders of magnitude more sensitive than ^{15}N NMR solid-state spectroscopy (Inbaraj *et al.*, 2006). Further, the TOAC label be placed at several positions along the helix and tilt angles can be determined more accurately. Future work could thus potentially resolve issues related to WALP/KALP helical tilt as mentioned in Section 4.1.

10.5
Elastic Membrane Deformations and Lipid–Protein Interactions

The hydrophobic matching between lipids and proteins, which entails a hydrophobic coupling between the bilayer mechanical properties of protein function, implies that the hydrophobic bilayer thickness d close to the protein inclusion should closely match the hydrophobic length l of the protein. This matching serves to minimize the energetic penalty associated with exposing hydrophobic lipid or protein moieties to the aqueous phase (see Figure 10.1). If $l \neq d_0$ (the bilayer equilibrium thickness), then $d \neq d_0$, that is, the "soft" bilayer responds to the presence of the "rigid" inclusion. Thus the bilayer deformation generally will involve both CE and SD of the lipid acyl chains in the two opposing monolayers.

Even though the bilayer can be considered as soft, the mechanical properties of lipid bilayers, nevertheless, entail that the bilayer deformation energy can regulate protein function by affecting the free energy associated with protein conformational changes ΔG_{int}, which has contributions from both the protein and the deformation energy of the bilayer ΔG_{def} (Andersen and Koeppe, 2007; Andersen *et al.*, 1999):

$$\Delta G = \Delta G_{\text{int}} + \Delta G_{\text{def}} \tag{8}$$

This regulation is bidirectional: the lipid bilayer can respond to a protein, whereas the protein may in turn respond to the bilayer by adjusting its conformation (effective hydrophobic dimensions) or in the case of single spanning α-helices, its helical tilt relative to the bilayer normal.

10.5.1
Quantifying Bilayer Deformation Energy

The bilayer deformation energy can be estimated using the continuum theory of elastic bilayer deformations (Huang,

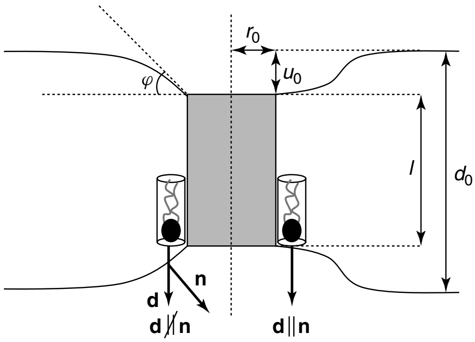

Fig. 10.3 Inclusion-induced bilayer deformation. The total deformation free energy is determined by the bilayer deformation profile associated with a hydrophobic mismatch between the bilayer and the inclusion. The inclusion is treated as a rotationally symmetrical deformation of the bilayer. Assuming midplane symmetry (a symmetrical bilayer), the problem can be reduced to a radially varying deformation of a monolayer with unperturbed thickness $d_0/2$, where $u(r)$ denotes the local perturbation in monolayer thickness at the distance r from the luminal axis. At the channel–bilayer contact surface, r_0, the deformation is u_0. The first derivative at the contact surface (the contact slope) du/dr is $s = \tan(\varphi)$. The deformation profile to the left of the inclusion corresponds to $\mathbf{d} \neq \mathbf{n}$ and $s = s_{\rm min}$, the profile to the right of the protein correspond to $\mathbf{d} = \mathbf{n}$ and $s = 0$. The deformation profiles obtained using the elastic membrane model define the average hydrocarbon/headgroup boundary. The actual (instantaneous) profile will be less well-defined due to thermal motion of the bilayer lipids perpendicular to the bilayer/solution interface (Wiener and White, 1992).

1986; Helfrich and Jakobsson, 1990). The energy density has contributions from CE (Eq. (2)) and bending (Eq. (3)). Combining these contributions, the total free energy of deformation for a cylindrical protein with radius r_0 can be written as

$$\begin{aligned}\Delta G_{\rm def} = {}& \frac{1}{2}\int_{r_0}^{\infty}\left[K_a\left(\frac{2u}{d_0}\right)^2 + K_c(c_1\right.\\ &\left. + c_2 - c_0)^2 + \Gamma\left(\frac{du}{dr}\right)^2\right]2\pi r dr\\ &- \frac{1}{2}\int_{r_0}^{\infty} K_c c_0^2 2\pi r dr \pi \int_{r_0}^{\infty}\\ &\times\left[K_a\left(\frac{2u}{d_0}\right)^2 + K_c(c_1 + c_2)^2\right.\\ &\left. - K_c(c_1 + c_2)c_0 + \Gamma\left(\frac{du}{dr}\right)^2\right] r dr\end{aligned} \tag{9}$$

where $c_1 = 1/R_1$ and $c_2 = 1/R_2$. To determine the minimal free energy, one must minimize Eq. (9) with respect to variations in $u(r)$. Four boundary conditions are needed to solve Eq. (9).

Three of these are self-evident. Far away from the protein $u = 0$ and $du/dr = 0$ for $r \to \infty$. Close to the protein, hydrophobic matching implies that $u(r_0) = (d_0 - 1)/2$. The fourth boundary condition $du/dr(r = r_0) = s = \tan(\varphi)$ can be formulated in several ways (Huang, 1986; Helfrich and Jakobsson, 1990). Two extreme cases can be considered (Nielsen, Goulian and Andersen, 1998). A “free slope” boundary condition, is one where the slope is free to assume a value that will minimize s. This $s = s_{\rm min}$ condition implies that the lipids are allowed to tilt, that is, have their director **d** deviating from the bilayer surface normal vector **n**. The other extreme case is a "constrained slope" boundary condition, which generally implies that $\mathbf{d}|\mathbf{n}$ and specifically for cylindrical inclusion, $s = 0$ (see Figure 10.3).

It turns out that the c_1c_2-dependent Gaussian term can be neglected (Nielsen and Andersen, 2000) and that the c_0-dependent term in Eq. (9) only depends on s (Ring, 1996) corresponding to an energy term

$$\Delta G_{\mathrm{MEC}} = 2\pi K_c r_0 s c_0 \tag{10}$$

Thus, we may minimize ΔG_{def} by first solving the Lagrange equation corresponding Eq. (9) with $c_0 = 0$, and subsequently adding ΔG_{MEC} to the total minimized ΔG_{def}. The Lagrange equation is

$$K_c\nabla^4 u - \Gamma\nabla^2 u - (K_a/d_0^2)u = 0 \tag{11}$$

From Eq. (11), a solution can be obtained analytically (Nielsen, Goulian and Andersen, 1998) as

$$\Delta G_{\mathrm{def}} = \pi r_0 K_c \left[s\left[\frac{A_+K_0\left(\frac{\sqrt{i}r_0}{\lambda}\right) - A_-K_0\left(\frac{\sqrt{-i}r_0}{\lambda}\right)}{i\lambda^2}\right] + u_0\left[\frac{A_+K_1\left(\frac{\sqrt{i}r_0}{\lambda}\right) + iA_-K_1\left(\frac{\sqrt{-i}r_0}{\lambda}\right)}{\sqrt{i}\lambda^3}\right] + \Gamma u_0 s \right] \tag{12}$$

where K_0 and K_1 are the modified first-order Bessel functions of the second kind and

$$\lambda = \sqrt[4]{\frac{d_0^2 K_c}{K_a}} \tag{13a}$$

and

$$A_+ = \frac{u_0K_1\left(\frac{\sqrt{-i}r_0}{\lambda}\right) - sK_0\left(\frac{\sqrt{-i}r_0}{\lambda}\right)\frac{\lambda}{\sqrt{-i}}}{K_0\left(\frac{\sqrt{i}r_0}{\lambda}\right)K_1\left(\frac{\sqrt{-i}r_0}{\lambda}\right) - iK_0\left(\frac{\sqrt{-i}r_0}{\lambda}\right)K_1\left(\frac{\sqrt{i}r_0}{\lambda}\right)} \tag{13b}$$

and

$$A_- = \frac{-iu_0K_1\left(\frac{\sqrt{i}r_0}{\lambda}\right) - sK_0\left(\frac{\sqrt{i}r_0}{\lambda}\right)\frac{\lambda}{\sqrt{-i}}}{K_0\left(\frac{\sqrt{i}r_0}{\lambda}\right)K_1\left(\frac{\sqrt{-i}r_0}{\lambda}\right) - iK_0\left(\frac{\sqrt{-i}r_0}{\lambda}\right)K_1\left(\frac{\sqrt{i}r_0}{\lambda}\right)} \tag{13c}$$

Rewriting, we get

$$\begin{aligned}\Delta G_{\mathrm{def}} &= -\pi r_0 K_{\mathrm{c}} \\ &\left[\frac{u_0^2[K_1(r_0/(\sqrt{-i}\lambda))K_1(r_0/\sqrt{i}\lambda) - K_1(r_0/(\sqrt{i}\lambda))K_1(r_0/\sqrt{-i}\lambda)]/\lambda^4}{K_0(r_0/\sqrt{i}\lambda)K_1(r_0/(\sqrt{-i}\lambda))/(\sqrt{-i}\lambda) - K_0(r_0/\sqrt{-i}\lambda)K_1(r_0/(\sqrt{i}\lambda))/(\sqrt{i}\lambda)}\right. \\ &+ \frac{su_0[K_0(r_0/(\sqrt{-i}\lambda))K_1(r_0/\sqrt{i}\lambda) - K_1(r_0/\sqrt{i}\lambda)K_0(r_0/\sqrt{-i}\lambda)]/(\sqrt{i}\lambda^3)}{K_0(r_0/\sqrt{i}\lambda)K_1(r_0/(\sqrt{-i}\lambda))/(\sqrt{-i}\lambda) - K_0(r_0/\sqrt{-i}\lambda)K_1(r_0/(\sqrt{i}\lambda))/(\sqrt{i}\lambda)} \\ &+ \frac{s^2[K_0(r_0/\sqrt{-i}\lambda)K_0(r_0/\sqrt{i}\lambda) - K_0(r_0/\sqrt{i}\lambda)]K_0(r_0/\sqrt{-i}\lambda)]/\lambda^2}{K_0(r_0/\sqrt{i}\lambda)K_1(r_0/(\sqrt{-i}\lambda))/(\sqrt{-i}\lambda) - K_0(r_0/\sqrt{-i}\lambda)K_1(r_0/(\sqrt{i}\lambda))/(\sqrt{i}\lambda)} \\ &\left. + \Gamma u_0 s\right] \qquad (14)\end{aligned}$$

For realistic values of Γ, it turns out that the relative energetic contribution from surface tension can be neglected (Nielsen, Goulian and Andersen, 1998). Consequently Eq. (14) is effectively biquadratic in u_0 and s.

$$\Delta G_{\mathrm{def}}(u_0, s) = a_1 u_0^2 + a_2 u_0 s + a_3 s^2 \qquad (15)$$

For both $s = s_{\min}$ and $s = 0$, Eq. 15 reduces to a linear spring formalism with a phenomenological coefficient H

$$\Delta G_{\mathrm{def}} = H(2u_0)^2 \qquad (16a)$$

With $$H_{s=s_{\min}} = a_1 - a_2^2/4a_3 \qquad (16b)$$

and $$H_{s=0} = a_1/4, \qquad (16c)$$

respectively. In general, with the added ΔG_{MEC} contribution we get

$$\begin{aligned}\Delta G_{\mathrm{def}}(u_0, s) &= a_1 u_0^2 + a_2 u_0 s + a_3 s^2 \\ &\quad + 2\pi K_c r_0 s c_0 \qquad (17)\end{aligned}$$

where the a coefficients are functions of the material moduli, bilayer thickness, and inclusion (protein) radius. Equation (17) can be re-written as

$$\begin{aligned}\Delta G_{\mathrm{def}}(u_0, s) &= a_1 u_0^2 + (a_2 u_0 \\ &\quad + 2\pi K_c r_0 c_0)s + a_3 s^2 \qquad (18)\end{aligned}$$

For both free and constrained slope boundary conditions we can write ΔG_{def} as

$$\begin{aligned}\Delta G_{\mathrm{def}} &= H_B(d_0 - l)^2 \\ &\quad + H_X(d_0 - l)^2 c_0 + H_C c_0^2 \\ \Delta G_{\mathrm{def}} &= H_b(d_0 - l)^2 \\ &\quad + H_X(d_0 - l)^2 c_0 + H_C c_0^2 \qquad (19)\end{aligned}$$

where H_B, H_X and H_C are functions of the a coefficients, r_0, and K_c (Andersen and Koeppe, 2007; Nielsen and Andersen, 2000).

Formally, we can express the coefficients in Eq. (18) as

$$a_{\mathrm{i}} = K_{\mathrm{c}} r_0 f_{\mathrm{i}}(r_0/\lambda) \qquad (20)$$

where

$$f_1(r_0/\lambda) = \frac{\pi[K_1(r_0/(\sqrt{-i}\lambda))K_1(r_0/\sqrt{i}\lambda) - K_1(r_0/(\sqrt{i}\lambda))K_1(r_0/\sqrt{-i}\lambda)]/\lambda^4}{K_0(r_0/\sqrt{i}\lambda)K_1(r_0/(\sqrt{-i}\lambda))/(\sqrt{-i}\lambda) - K_0(r_0/\sqrt{-i}\lambda)K_1(r_0/(\sqrt{i}\lambda))/(\sqrt{i}\lambda)} \tag{21a}$$

$$f_2(r_0/\lambda) = \frac{\pi[K_0(r_0/(\sqrt{-i}\lambda))K_1(r_0/\sqrt{i}\lambda) - K_1(r_0/\sqrt{i}\lambda)K_0(r_0/\sqrt{-i}\lambda)]/(\sqrt{i}\lambda^3)}{K_0(r_0/\sqrt{i}\lambda)K_1(r_0/(\sqrt{-i}\lambda))/(\sqrt{-i}\lambda) - K_0(r_0/\sqrt{-i}\lambda)K_1(r_0/(\sqrt{i}\lambda))/(\sqrt{i}\lambda)} \tag{21b}$$

$$f_3(r_0/\lambda) = \frac{\pi[K_0(r_0/\sqrt{-i}\lambda)K_0(r_0/\sqrt{i}\lambda) - K_0(r_0/\sqrt{i}\lambda)]K_0(r_0/\sqrt{-i}\lambda)]/\lambda^2}{K_0(r_0/\sqrt{i}\lambda)K_1(r_0/(\sqrt{-i}\lambda))/(\sqrt{-i}\lambda) - K_0(r_0/\sqrt{-i}\lambda)K_1(r_0/(\sqrt{i}\lambda))/(\sqrt{i}\lambda)} \tag{21c}$$

Equations (15)–(21) constitute a general formalism in which bilayer deformation energy can be estimated using estimates for K_a, K_c, d_0, l, r_0, c_0, and s. It is important to note that ΔG_{def} arises as a minimization of Eq. (9) for both the constrained and relaxed boundary condition (Nielsen, Goulian and Andersen, 1998). This implies that the energy components (CE and bending) are interrelated and one cannot interpret ΔG_{def} (and the resulting bilayer deformation profile) as arising from only one energy component or descriptor (e.g. thickness or curvature) of bilayer properties.

10.5.2
Bilayer Deformation Energy and Protein Function

Reliable quantification of bilayer deformation energies is based on macroscopic bilayer parameters K_a, K_c, and c_0. This raises two concerns: are macroscopic parameters valid in a description of bilayer deformations on length-scales corresponding to the radial extent of annular lipids (see Section 4.2) or the bilayer thickness? If they are, how will experimental uncertainties in these parameters affect the estimate for ΔG_{def}? and thus any predictions of how the bilayer may regulate protein function? Furthermore, are there experimental model systems in which the elastic theory and ΔG_{def} estimates can be evaluated?

10.5.2.1 Model Systems

A useful experimental tool for investigating elastic bilayer formation takes advantage of the unique formation of gramicidin ion channels in lipid bilayers (Andersen *et al.*, 1999; Huang 1986; Goulian *et al.*, 1998; Lundbaek and Andersen, 1999). Gramicidin channels are formed by transmembrane dimerization of two nonconducting $\beta^{6.3}$-helical subunits (O'Connell, Koeppe and Andersen, 1990) (see Figure 10.4). They are permeable to monovalent cations and channel formation (channel average lifetimes) is detectable using standard voltage clamp techniques (Andersen, 1983). As the hydrophobic length of the gramicidin dimer (22 Å) is shorter than the

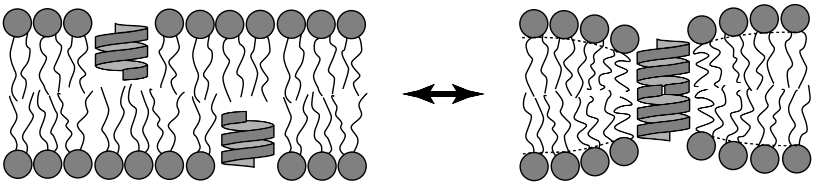

Fig. 10.4 Gramicidins as molecular force transducers. Two nonconducting dimers (left) join and form a channel (right). Because channel formation involves a well-defined deformation of the bilayer, the gramicidin channel average lifetime, which is detectable using standard voltage-clamp techniques, will vary as a function of the hydrophobic mismatch through Eq. (22) (Andersen and Koeppe, 2007; Andersen, 1999).

hydrophobic thickness of the bilayer (which in turn is dependent on, e.g., acyl chain length and solvent properties), channel formation leads to a well-defined deformation of the bilayer. Thus gramicidin can be used as molecular force transducers (Andersen *et al.*, 1999) detecting the disjoining force on the dimer exerted by the bilayer:

$$\begin{aligned} F &= -\left(-\frac{\partial \Delta G}{\partial (d_0 - l)}\right) \\ &= 2H_B(d_0 - l) + H_X c_0 \qquad (22) \end{aligned}$$

The elastic description has been tested using gramicidins as a function of changes in d_0 implemented as changes in acyl chain length and alkane solvent length (Huang 1986; Lundbaek and Andersen, 1999; Elliott *et al.*, 1983) or tension (effectively thinning the bilayer) (Goulian *et al.*, 1998).

Using independently determined values for the mechanical moduli, quantitative agreement could be obtained (Goulian *et al.*, 1998; Lundbaek and Andersen, 1999) assuming that the energetic cost of tilt ($\mathbf{d} \not\parallel \mathbf{n}$) is high, thereby effectively constraining the lipid packing close to the protein and increasing ΔG_{def} (Huang, 1986; Lundbaek and Andersen, 1999). Although the "conformational change" involved in gramicidin channel dimerization is unique and the dimerization always is associated with a dimpling of the bilayer, gramicdins, nevertheless, can be used to quantify the deformation energy (i.e. the phenomenological spring constants).

10.5.2.2 **Integral Membrane Proteins**

As described in Section 10.4, the structures and conformational changes involved in function of integral proteins are generally difficult to detect in fluid lipid bilayers. While β-barrel proteins appear to be rather "inert" in the sense that their function is unlikely to involve major conformational changes, the function of α-helical bundle proteins is likely to involve sliding and tilting of their transmembrane segments (Unwin, 1989; Kaback and Wu, 1997; Sakmar, 1998). Part of the free energy for these conformational changes depends on intrinsic protein factors (Eq. (8)) such as unbinding of the helix–helix association motif (see Section 10.3.2.2). The open–close transition in gap junction channels, for example, involves a tilt of the domains by about 8° (Unwin and Ennis, 1984) corresponding to a hydrophobic length change of 0.3 Å. Both the open and closed states are likely to perturb the bilayer with deformation energies $\Delta\Delta G_{\text{def,o}}$ and $\Delta\Delta G_{\text{def,c}}$

$$\Delta\Delta G_{\text{def}} = \Delta G_{\text{def,o}} - \Delta G_{\text{def,c}} \qquad (23)$$

The closed → open transition probability is

$$P = \frac{1}{1 + K^*_{c\to 0}\exp(\Delta\Delta G_{\text{def}}/kT)} \qquad (24)$$

where $K^*_{c\to 0}$ is the intrinsic equilibrium constant of the transition. Equations (23) and (24) constitute the link between bilayer deformation energy (as determined by the bilayer material/elastic properties) and integral membrane protein function. The analysis shows that the energies can be considerable: for a protein embedded in a bilayer with an initial mismatch of 1 Å, an increase to 1.3 Å increases P by 10-fold (Nielsen, Goulian and Andersen, 1998). Also recent NMR studies on rhodophsin show that the protein can adjust its helical content to match changes in bilayer hydrophobic thickness (Soubias *et al.*, 2008) showing that deformation energies are sufficient to change H-bonding patterns and that the hydrophobic matching is reciprocal: both protein and bilayer can respond to it.

The link between ΔG_{def} and protein function (Eqs (23) and (24)) reflects not only hydrophobic matching but also the hydrophobic coupling between bilayer material properties and membrane protein function. Using this framework as a basis, it is possible to rationalize the effect on protein function of *changing* the bilayer material moduli (e.g. by incorporating pharmacological amphiphatic compound), for a comprehensive overview see Lundbaek (2006).

10.6
Summary and Perspectives

Support for a physical (mechanical) view of the membrane comes from reconstitution experiments where membrane proteins can be inserted into lipid bilayers consisting of only one or a few lipid species, for example, see Criado, Eibl and Barrantes (1984); Johannsson, Smith and Metcalfe (1981). This suggests that membrane protein function is not necessarily crucially dependent on specific lipid–protein interactions. Nevertheless, the function of many different types of bilayer embedded proteins can be modulated by maneuvers that changes bilayer mechanical properties, see Andersen and Koeppe (2007) and references therein.

The elastic description of protein-induced bilayer deformation provides a strong basis for understanding how the bilayer can regulate protein function. This understanding is both qualitative and quantitative. With calculated deformation energies, it is possible to predict how the bilayer properties and, in particular, how induced changes in these properties will affect protein function. However, it is important to stress the energetic consequences of lipid packing around the protein. The effective packing translates into an effective slope at the protein-bilayer boundary, which again determines ΔG_{def}. In fact, $\Delta\Delta G_{\text{def}}(c_0)$ (Eq. (23)) and thus $P(c_0)$ (Eq. (24)) can be either increasing or decreasing functions of c_0 dependent on the choice of boundary condition (Nielsen and Andersen, 2000). Among the future challenges is the need for a better understanding of the energetic consequences of local lipid packing and more specific interactions. Binding of lipids in crystal structures of membrane proteins as seen, for example, for bacteriorhopsin (Corcelli *et al.*, 2002), photosynthetic reaction centers (Nogi *et al.*, 2000; Fyfe *et al.*, 2004), and aquaporin (Gonen *et al.*, 2005) could be taken as evidence for specific lipid–protein interactions, but for lipids binding so tightly, they should, in fact, be regarded as structural cofactors (Lee, 2005).

The fact that the membrane deformation energy is an unspecific regulator of protein function depending on local lipid packing around the protein also resolves the apparent problem that a stored elastic energy (curvature-stress) is a thermodynamic property of the entire bilayer. Thus, any change in the bilayer deformation energy would change the conformational equilibrium of all proteins in a cell membrane, which would compromise the cell's control of the membrane and its function. This would indeed be the case if all proteins were having similar hydrophobic shapes and thus "felt" the deformation energy in the same manner through similar boundary conditions and the membrane has a uniform structure. The increasing number of high-resolution membrane protein structures shows that despite obvious similarities (e.g. the occurrence of interfacial aromatic residues) transmembrane protein structures display a substantial structural variety on the Å to nanometer scale. Also, despite considerable controversies, there is evidence that the lateral heterogeneity of the membrane leads to various domains with different lipid–protein composition and thus mechanical properties (Simons and Ikonen, 1997; Brown and London, 1998; Jacobson, Mouritsen and Anderson, 2007; Edidin, 2003). Thus, although a general change in the bilayer deformation energy is global, the "sensing" of this energy is different for different protein structures located in different domains (Lundbaek *et al.*, 2003). Nevertheless the general mechanism is the same: hydrophobic matching leads to hydrophobic coupling between protein function and bilayer properties and the energies involved are of sufficient magnitude to regulate protein structure and function.

11.1
Introduction

Encoded in the strings of DNA bases that make up the genomes of living species are codes that regulate, control, and describe all sorts of biological processes. The underpinnings of these codes lie in the base sequence-dependent micromechanical properties of DNA, which determine the degree to which the long, threadlike molecule fluctuates and how it responds to the proteins that control its processing and govern its packaging.

Insight into these properties of DNA comes from a variety of sources, ranging from classical physical measurements of polymeric behavior to new biophysical techniques that allow for the manipulation of single DNA molecules and new computational approaches that incorporate the sequence-dependent structural and energetic information encoded in high-resolution DNA structures. This chapter first introduces the reader to the classic representation of DNA as an elastic rod and the breakdown of this model in the interpretation of recent experimental data. Next follows an overview of the classical physical–chemical perspective of DNA mechanics in terms of its polyanionic character and fiber-diffraction properties and a summary of early ideas on the connection of base sequence to helical structure and DNA bending. The narrative then turns to the unique, sequence-dependent spatial information that has been gleaned from the many solved crystal structures of DNA and its complexes with other molecules. Following a brief discussion of the knowledge-based elastic functions that incorporate the observed sequence-dependent structural properties of DNA, the chapter concludes with examples of some of the new insights into DNA polymeric behavior gained with new computational approaches that incorporate the sequence-dependent features of neighboring base-pair steps.

11.2
DNA Elastic Rod

Although the biological literature tends to focus on the double-helical structure of short pieces of DNA, the classic physics literature dwells on the macroscopic properties of DNA and the thin, inextensible, naturally straight, homogeneous elastic-rod model (Kirchhoff, 1859, 1876) used to interpret the features of

Handbook of Molecular Biophysics. Methods and Applications. Edited by Henrik G. Bohr.

ISBN: 978-3-527-40702-6

very long molecules. The elastic energy of the rod is taken as the integral of a bending energy that depends on the curvature κ of the smoothly deforming structure and a twisting contribution that depends on the difference, $\Delta\omega$, between the twist of residues in the stress-free state and the current state,

$$E = \frac{A}{2}\int_0^L \kappa(s)^2 ds + \frac{C}{2}\int_0^L \Delta\omega(s)^2 ds \tag{1}$$

Here s is the arc length, L the contour length, A the bending modulus, and C the torsional modulus of the rod.

The bending constant A is directly proportional to the persistence length a, a measure of DNA extension found from both classic (Hagerman, 1988; Crothers *et al.*, 1992; Bednar *et al.*, 1995) and single-molecule (Smith, Finzi and Bustamante, 1992; Baumann *et al.*, 1997) experiments to be in the range of 500–600 Å for mixed sequence DNA under physiological salt conditions, that is $A = ak_BT$, where k_B is the Boltzmann constant and T the temperature in Kelvin. The magnitude of the torsional modulus, however, is a matter of debate. Values of C obtained with recent rotor-bead tracking measurements (Bryant *et al.*, 2003) ($4.1 \pm 0.3 \times 10^{-19}$ erg cm) substantially exceed the values deduced from many solution studies (Barkley and Zimm, 1979; Thomas *et al.*, 1980; Hurley *et al.*, 1982; Millar, Robbins and Zewali, 1982; Horowitz and Wang, 1984; Heath *et al.*, 1996), but roughly match the values extracted from the observed populations (Shore and Baldwin, 1983) of short, covalently closed DNA duplexes with different linking numbers. Proponents of the solution data suggest that bending strain restricts the twisting of small, circular molecules (Heath *et al.*, 1996) and also note the closer correspondence of the observed ratio of the bending and twisting moduli, A/C, deduced from the solution data with the predicted value of 1.5 for an incompressible rod. That is, under conditions where the persistence length is 500 Å and the bending constant A is 2×10^{-19} erg-cm, the ratio A/C is roughly unity when the torsional modulus is based on the solution data, but ~0.5 when the higher estimates of C are used. Moreover, the negative Poisson ratio σ deduced from the latter values, $\sigma = A/C - 1$, is indicative of a thickening of the rod upon extension, a behavior unknown in homogeneous, isotropic elastic materials and also inconsistent with the structural properties of double-helical DNA (Kosikov *et al.*, 1999).

Measurements of the response of individual DNA molecules to imposed forces have stimulated extension of the elastic theory to account for the extensibility of DNA in terms of a stretching modulus S that measures the resistance of the polymer to longitudinal deformation (Odijk, 1995; Marko and Siggia, 1995). Application of the theory to these experiments yields S values of ~1000 pN when the persistence length is 500 Å. The derived variation of S with changes in ionic strength, however, does not match theoretical expectations. Although the theory predicts S to be directly proportional to the persistence length, the apparent stretching modulus decreases under conditions that increase a and vice versa (Baumann *et al.*, 2000).

Other indication of the breakdown of the DNA elastic-rod model comes from the unexpected, spontaneous cyclization of DNA molecules less than 100 bp in length (Cloutier and Widom, 2004, 2005). The observed levels of closed circular molecules, as measured by the Jacobson–Stockmayer *J* factor, the well-known ratio of the equilibrium constants for cyclization versus bimolecular association of a linear molecule (Jacobson and Stockmayer, 1950), are up to five orders of magnitude greater than those expected for a short DNA chain modeled as an ideal elastic rod (Shimada and Yamakawa, 1984). Both the apparent resistance of DNA to bending and the contributions of twist that bring the ends of the duplex in register for ring closure are much smaller than the elastic moduli cited above. Importantly, the sequences found to close most easily into tight minicircles contain a well-known nucleosome-positioning sequence (Lowary and Widom, 1998), that is a sequence that binds more tightly than others on the surface of the nucleosome core particle, with periodically repeating chemical features. This sequence includes two notable patterns: (i) TA base-pair steps, which recur at increments of ~10 bp, that is roughly every complete double-helical turn, and (ii) AT-containing dimers (AA, TA, or TT), which alternate at half-helical turns with GC base-pair steps. The classic theory takes no account of the special features of these steps that may give rise to the aberrant ring-closure properties.

11.3
Physical–Chemical Perspectives of DNA

11.3.1
DNA Polyanion

Of course, there is no reason other than mathematical convenience to assume that double-stranded DNA, with complementary antiparallel strands wrapped around a core of Watson–Crick base pairs (Figure 11.1), should behave like an inextensible elastic rod. The sugar–phosphate linkage acts like a spring in the sense that it constrains the movements of neighboring base pairs, with the

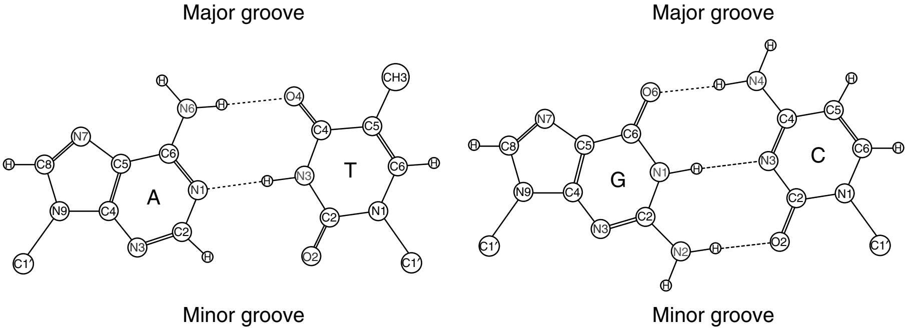

Fig. 11.1 Comparison of hydrogen-bonding interactions and chemical structures (including double bonds) of the purine and pyrimidine bases comprising normal A.T and G.C Watson–Crick pairs. Hydrogen bonds designated by dashed lines. Proton donor and acceptor atoms denoted in red and blue, respectively. Note the pseudosymmetric positioning of the purine N3 and pyrimidine O2 atoms on the minor-groove edges of the base pairs and the unique sequence-dependent signatures (Seeman, Rosenberg and Rich, 1976) of the unfulfilled donor and acceptor atoms on the major-groove edges of A.T versus G.C. (Please find a color version of this figure on the color plates.)

repulsive interactions between the negatively charged phosphates helping to maintain the straight helical structure (Manning, 2006). Neutralization of the charge, such as by deposition of DNA on positively coated surfaces (Podestà *et al.*, 2005), has a dramatic effect on polymer extension, decreasing the persistence length by fivefold. Asymmetric reduction of charge, by site-specific neutralization of phosphates on one face of the DNA (Strauss and Maher, 1994), similarly bends the duplex toward the chemically modified sites. The nonuniform build-up of counterions in the grooves of DNA (Williams and Maher, 2000) presumably bends the double helix along the same lines, with the preferential localization of positively charged species in the major groove of G.C-rich sequences (Denisov and Halle, 2000) and the minor groove of A.T-rich sequences (Hud and Feigon, 1997) governing the intrinsic structure and deformability (see Figures 11.1 and 11.2 and discussion below of the DNA grooves).

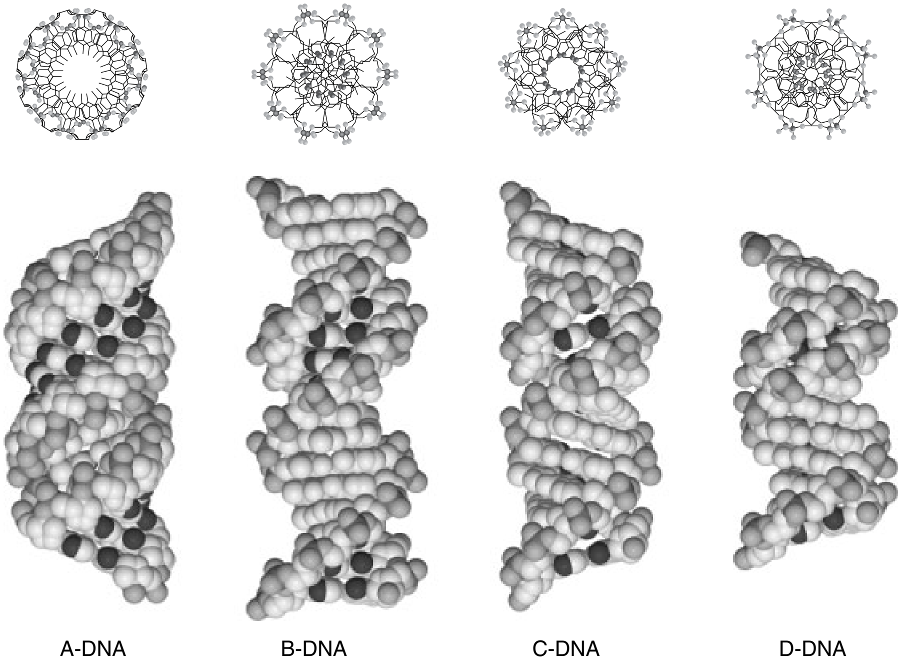

Fig. 11.2 Top and side views illustrating the global features of selected right-handed double-helical models deduced from X-ray fiber-diffraction measurements: A-DNA (Franklin and Gosling, 1953), 11 bp/helical turn; B-DNA (Watson and Crick, 1953), 10 bp/helical turn; C-DNA (Marvin *et al.*, 1958), 9 bp/helical turn; D-DNA (Davies and Baldwin, 1963), 8 bp/helical turn. The dark balls, located on the purine N3 and pyrimidine O2 atoms, reveal the relative exposure of the minor-groove edges of the Watson–Crick base pairs in the different helical forms. The lighter balls, located on the phosphate groups, help to visualize the accompanying changes in groove widths. DNA is represented by stick models and smaller balls on the aforementioned atoms in the top views, and by regular space-filling models in the side views. Note, in addition, the differences in base-pair inclination, width of the central "channel," and overall DNA extension. Images rendered with Raster3D (Merritt and Bacon, 1997).

11.3.2
DNA Fiber-Diffraction Models

The classic models of stretched DNA fibers provide hints of the ways in which the double-helical structure responds to changes in chemical environment. For example, variation in the ion composition or water content of DNA fibers introduces a large-scale conformational rearrangement of the classic right-handed B-DNA double helix with 10 bp per turn (Watson and Crick, 1953) to under- and over-wound A-DNA, C-DNA, and D-DNA structures of the same helical sense with 11, 9, and 8 bp per turn, respectively (Franklin and Gosling, 1953; Marvin *et al.*, 1958; Davies and Baldwin, 1963) (Figure 11.2). These changes in helical repeat are coupled to changes in the inclination and displacement of base pairs, which are linked, in turn, to the helical pitch and groove structure. Although the planes of the Watson–Crick base pairs stack roughly perpendicular to the global helical axis of B-DNA, they deviate by 10–20° from this alignment in the A, C, and D forms. Inclination of this magnitude, when coupled to the movement of the base pairs toward the outside of the helix, reduces the pitch, that is the projected displacement of successive base pairs along the global helical axis, and brings different atoms to the surface of the helix. Although the edge of the Watson–Crick base pair containing the pyrimidine O2 and the purine N3 atoms, also called the *minor-groove edge,* is exposed, the edge on the opposite side of the base pair, called the *major-groove edge,* is hidden in A-DNA compared to B-DNA (see Figures 11.1 and 11.2). By contrast, the minor groove is less accessible and the major groove is more accessible in C- and D-DNA compared to B-DNA. In other words, the B → A transition displaces and reorients base pairs in the opposite sense from that seen in the B → C and B → D transitions (Calladine and Drew, 1984; van Dam and Levitt, 2000; Vargason, Henderson and Ho, 2001; Lu and Olson, 2003). The displacement of base pairs also opens a channel through the center of the duplex during the course of these transitions. The atoms that line the inner passages provide potential binding sites for water, ions, and other small molecules from the surrounding environment.

11.3.3
Base Sequence and Helical Structure

The models of DNA deduced from the diffraction patterns of regularly repeating polynucleotide chains offered the first suggestions of a connection between base-pair sequence and three-dimensional double-helical structure (Chandrasekaran and Arnott, 1989). For example, the synthetic poly(dG)·poly(dC) homopolymeric complex is “A-philic” (Ivanov *et al.*, 1974) in the sense that it adopts an A-like structure under conditions where the poly(dA)·poly(dT) duplex is B-like (Arnott and Selsing, 1974a, 1974b). Moreover, poly(dA)·poly(dT) differs from canonical B-DNA in taking up a slightly modified B′ helical structure with highly distorted base pairs (Arnott *et al.*, 1983; Alexeev, Lipanov and Skuratovskii, 1987a, 1987b). Other sequences favor the C and D forms. For example, the repetition of A.T or I.C base pairs seems to accommodate the deep, tightly closed minor groove typical of D-DNA (Chandrasekaran and Arnott, 1989; Arnott, 1999; Premilat and Albiser, 1986). The purine rings of these two base pairs, adenine and inosine (also called *hypoxanthine*), do not contain the bulky amino group attached to the minor-groove edge of guanine (see Figure 11.1) and thus fit more easily in the close confines of a narrowed minor groove.

11.3.4
Helical Fragments and Bending

The alternation of different helical forms along the DNA sequence, such as the insertion of an A-type stretch of GG·CC steps within a B-like duplex, not only brings selected base atoms to the surface for easy recognition by other molecules but also introduces an appreciable bend in the molecule (Selsing *et al.*, 1979) without disruption of base stacking, that is the characteristic van der Waals' association of neighboring base-pair planes one above the other. Bending of this sort is maximized when the deformed segment spans roughly a half-helical turn and forms a distinct wedge (Figure 11.3). The abutment of the inclined base pairs of a 5-bp fragment of A-DNA or C-DNA next to the base pairs of a B-type model introduces a bend of more than 20°, that is a change of this magnitude in the direction of the DNA axis. The bending would be even more pronounced if ~5-bp segments of A- and C- or D-like structures were repeated in tandem, forming bends of ~45° per 10-bp fragments and superhelical structures with ~80 bp per turn (Figure 11.3). Models of this type were initially used to account for the "action-at-a-distance" effects,

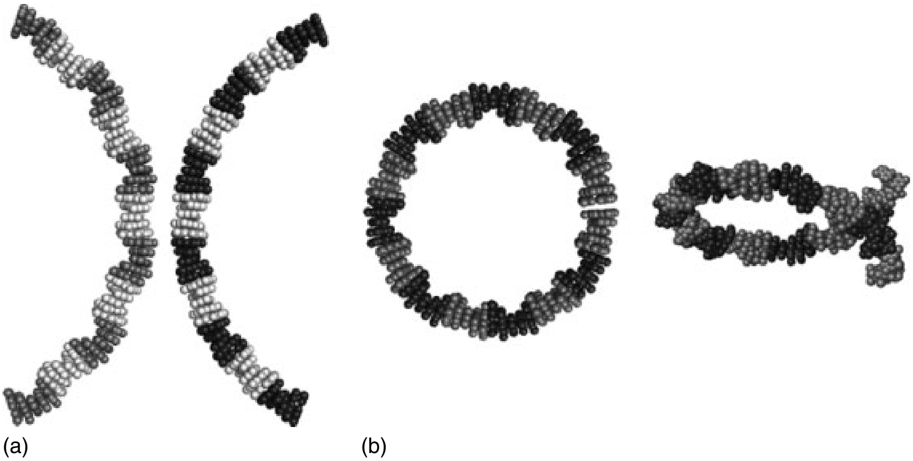

Fig. 11.3 Schematic illustration of curved DNA structures generated by the repeated abutment of 5-bp stretches of A-, B-, and C-like helices: (a) views down the global axes of semicircular structures constructed of (left) A/B and (right) B/C wedges; (b) views down and perpendicular to the axis of the tight superhelical pathway, with nearly 80 bp/superhelical turn, constructed of A/C wedges. The alignment of the structures in (a), along the central B-DNA stretch of each fragment, emphasizes their similar 150-bp circular curvature and opposing directions of global bending. Structures generated with the 3DNA software package, with A-, B-, and C-like base pair steps assigned (roll and slide) values of (7.4°, −1.2 Å), (0°, 0 Å), and (−7.4°, 1.2 Å), respectively. Tilt, twist, shift, and rise are fixed at 0°, 36°, 0 Å, and 3.4 Å throughout. Images prepared using PyMOL (DeLano, 2002).

for example melting enhancement and binding affinities, observed spectroscopically (Burd *et al.*, 1975) in abutting helical segments of synthetic $C_nA_n \cdot T_nG_n$ block copolymers and subsequently confirmed by the coexistence of A and B helical forms in $d(G_nT_n) \cdot d(C_nA_n)$ oligodeoxynucleotides in solution (Early *et al.*, 1977; Wang *et al.*, 1987, 1989) and protein-bound DNA crystals (Lu, Shakked and Olson, 2000). The GC half of the latter molecules exhibits A-like spectra, whereas the AT fraction retains B-like properties in concentrated salt solution. The coexistence of A- and B-type helices is also relevant to the structure of hybrid DNA–RNA complexes in which the double-helical DNA segments adopt B-form helices and the complementary RNA and DNA residues associate as A-type structures (Saenger, 1984). The superhelical arrangement of abutting stretches of A- and C-DNA, shown here for the first time, resembles the pathway taken by DNA around the core of histone proteins in the nucleosome core particle (Luger *et al.*, 1997)

Structural Features of DNA

11.4.1
High-Resolution Structures

The variation of DNA helical form and global bending found in early fiber models is being revealed today at atomic resolution in an ever-growing number of high-resolution crystal structures of “pure” DNA oligomers and DNA complexes with proteins and/or drugs. As anticipated, these structures are base-sequence dependent, with individual residues assuming characteristic spatial forms. This section summarizes the simple picture of base-sequence-dependent DNA structure and deformability that has emerged from these data, with emphasis on the subtle changes in local conformation and flexibility associated with the sequential arrangement of the four common bases in the observed right-handed helices. The more dramatic conformational changes that give rise to the left-handed Z-DNA helical structure (Wang *et al.*, 1979; Gessner *et al.*, 1989) are not addressed here. Z-DNA belongs to a totally different class of double-helical structures, which is widely separated from A-, B-, C-, and D-DNA by conformational barriers substantially higher than those that partition the major right-handed helical forms (Harvey, 1983; Olson *et al.*, 1983). Indeed, many of the solution properties attributed to Z-DNA can be accounted for by left-handed forms of the A–D helices that differ only subtly, in terms of the arrangement of the sugar–phosphate backbone and glycosyl linkage between the sugar and base, from conventional right-handed DNA; see Olson (1982) for further details.

11.4.2
DNA Base-Pair Parameters

Among the most interesting aspects of the known high-resolution DNA structures are the subtle irregularities of the double helix dictated by the locations of purine and pyrimidine residues along the chain backbone. In order to examine these perturbations, Dickerson and Drew (1981) reintroduced several parameters originated by Arnott, Dover, and Wonacott (1969) to define the

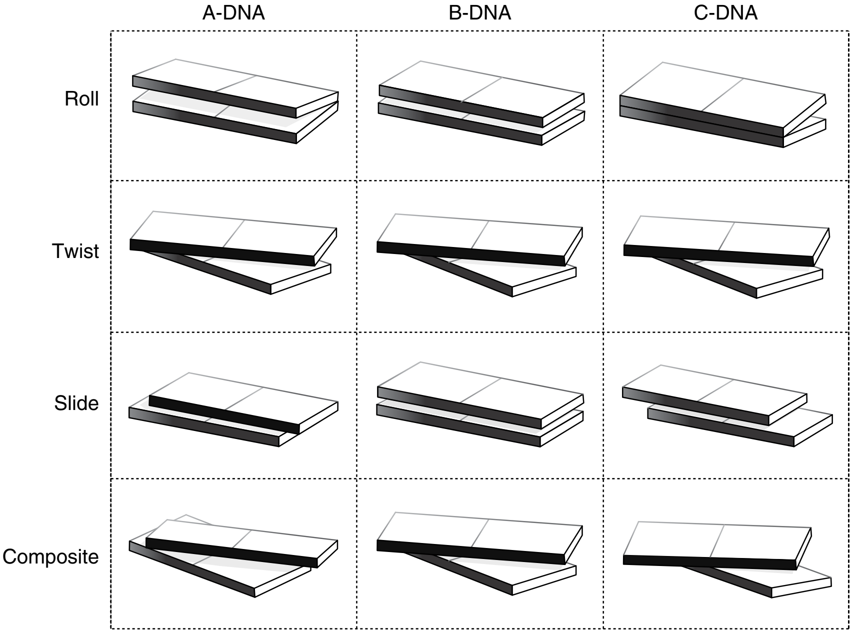

Fig. 11.4 Pictorial definitions of the three key rigid-body parameters – twist, roll, and slide – describing the spatial arrangements of sequential base pairs in DNA structures in A-, B-, and C-like steps. Base and base-pair ''bricks'' drawn such that the minor-groove edges are lightly shaded. Images generated with 3DNA (Lu and Olson, 2008), rendered with Raster3D (Merritt and Bacon, 1997), and plotted with PyMOL (DeLano, 2002).

orientation and displacement of adjacent base pairs in DNA fiber-diffraction models. The most important of these parameters for understanding the global helical transformations and sequence-dependent properties of DNA – twist, roll, and slide (Dickerson *et al.*, 1989) – are illustrated schematically in Figure 11.4. Twist is the rotation of successive base pairs about the normal to their planes, roll the rotation of the residues about the long axis of the dimer step, and slide the displacement of the base-pair centers parallel to the long axis. Variation in roll has a direct effect on the inclination of the DNA base pairs and the width of the major and minor grooves, while changes in slide alter the pitch and the depth of the grooves (Lu and Olson, 2003). Complete specification of DNA structure, however, requires knowledge, at each base-pair step, of (i) the six rigid-body parameters (buckle, propeller, opening, shear, stretch, and stagger) that describe the deviations of Watson–Crick base-pair geometry from the ideal planar form (Dickerson *et al.*, 1989), (ii) the three base-pair-step parameters (tilt, shift, and rise) that play a secondary role in most DNA structures (Dickerson *et al.*, 1989), and (iii) the set of torsion angles that describe the intervening sugar–phosphate linkages (IUPAC-IUB Joint Commission on Biochemical Nomenclature (JCBN), 1983). Tilt is the component of bending about the short axis of each dimer (an accordion-like deformation that concomitantly compresses and stretches the strands of an intact duplex), shift the displacement of successive base pairs along their short axis, and rise the vertical, that is van der Waals', spacing between the mean planes of the base pairs. Specification of the base positions places limits on the states of the backbone (Srinivasan and Olson, 1987) (also see below).

The values of the step parameters reported herein are based on the 3DNA suite of programs (Lu and Olson, 2003, 2008). The values are defined by a matrix-based scheme (Zhurkin, Lysov and Ivanov, 1979; Bolshoy *et al.*, 1991; El Hassan and Calladine, 1995) that is rigorous and reversible in that it allows for the exact reconstruction of a three-dimensional structure from a complete set of derived parameters. The right-handed coordinate frame attached to each base follows established guidelines (Olson *et al.*, 2001), with (i) the x-axis pointing in the direction of the major groove along what would be the pseudodyad axis of an ideal Watson–Crick base pair, that is the perpendicular bisector of the $C1' \cdots C1'$ vector spanning the base pair, (ii) the y-axis running along the long axis of the idealized base pair in the direction of the sequence strand, parallel to the $C1' \cdots C1'$ vector, and displaced so as to pass through the intersection on the (pseudodyad) x-axis of the vector connecting the pyrimidine Y(C6) and purine R(C8) atoms, and (iii) the z-axis is defined by the right-handed rule.

11.4.3
Bending and Translational Anisotropy

As implied above, twist, roll, and slide are more susceptible to variation than the three other base-pair-step parameters. The bending and translational anisotropy is evident in scatter plots of the bending angles and shear displacements found in 6606 dimer steps from a nonredundant set of 239 known protein–DNA crystal structures of 2.5 Å or better resolution taken from the Nucleic Acid Database (Berman *et al.*, 1992) (Figure 11.5). The range of observed roll values is many times that of tilt as evident from the relative lengths of the major and minor axes of the ellipses fitted to the data. The local bending flexibility suggested by the scatter of data, however, is somewhat deceptive since individual dimer sequences cluster in sequence-specific sectors of the roll–tilt ellipse (Olson *et al.*, 2008). The shear deformations plotted in Figure 11.5b similarly show greater variation of slide than shift, that is, preferential displacement along the long axes of base-pair steps, albeit with less striking directional differences than the angular deformations. The slide and shift values also group in sequence-specific zones.

11.4.4
Coupling of Parameters

Significantly, variations in roll and slide accompany changes in twist, with an increase in roll and a decrease in slide generally attended by a decrease in twist and vice versa. This conformational interdependence, which also occurs in the X-ray structures of "pure" DNA oligomers (Olson *et al.*, 1998), reflects the chiral nature of the dinucleotide linkage. That is, the constraints of chemical structure limit the range of sterically acceptable conformations and the routes

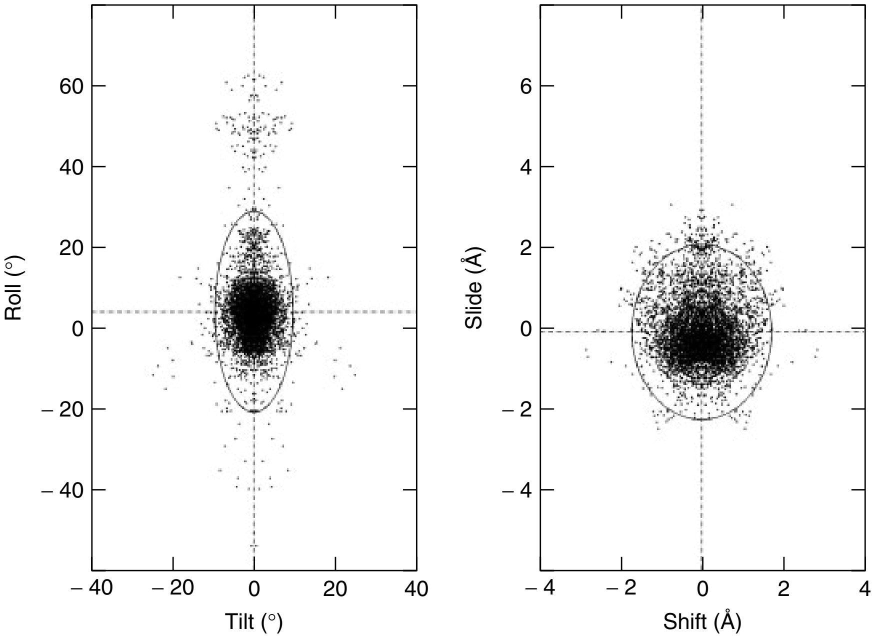

Fig. 11.5 Collective scatter plots of the tilt and roll bending angles (left) and the shift and slide shear displacements (right) in 6606 dimer steps from 239 protein–DNA crystal structures taken from the Nucleic Acid Database (Berman *et al.*, 1992).

by which they can be achieved. For example, the positive roll and negative slide values characteristic of A-DNA structures occur in concert with changes in the puckering of the sugar ring and the relative orientation of the sugar with respect to the base (Schneider, Neidle and Berman, 1997). The occurrence of high twist is often coupled to a conformational change of the phosphodiester backbone (Dickerson *et al.*, 1987), implicating the chemical pathway of duplex overwinding to a so-called $B_I \rightarrow B_{II}$ interconversion of the torsion angles about the C3′–O3′ and O3′–P bonds. Such B_{II} steps repeat at ~10-bp intervals in the nucleosome core particle structure (Richmond and Davey, 2003). Overtwisted states like these, with negative roll and positive slide, are identified with the C form of DNA (van Dam and Levitt, 2000).

11.4.5
Sequence-Dependent Twist

The sequence-dependent twisting observed in B-DNA and protein–DNA crystal structures (Gorin, Zhurkin and Olson, 1995; Olson *et al.*, 1998) mirrors simple geometrical features of the constituent base pairs; dimers with exocyclic groups involved in severe steric contacts in the major and minor grooves exhibit a tendency to unwind (Gorin, Zhurkin and Olson, 1995). These trends match the structural variability of dimer steps predicted over 25 years ago by Kabsch, Sander, and Trifonov (1982) from a combination of solution and gel

Tab. 11.1 Comparison of the sequence-dependent twist angles observed in high-resolution crystal structures with early predictions based on the gel and solution properties of DNA.[a]

Base-pair step	B-DNA[b]	P + DNA[c]	Prediction
	Purine–purine steps		
AG·CT	$28.5_{(5.3)}$	$32.2_{(5.1)}$	27.7
GG·CC	$35.3_{(5.4)}$	$33.2_{(4.4)}$	33.7
AA·TT	$36.1_{(3.1)}$	$32.6_{(6.8)}$	35.6

	Purine–pyrimidine steps		
AT·AT	$32.1_{(2.5)}$	$28.8_{(5.9)}$	31.5
AC·GT	$33.8_{(4.1)}$	$31.2_{(3.8)}$	34.4
GC·GC	$40.7_{(2.8)}$	$33.7_{(5.0)}$	40.0
	Pyrimidine–purine steps		
CG·CG	$31.7_{(5.7)}$	$33.5_{(4.6)}$	29.8
TA·TA	$41.9_{(6.7)}$	$35.6_{(8.9)}$	36.0
CA·TG	$42.4_{(8.7)}$	$36.1_{(6.4)}$	34.5

[a] Twist values, in degrees, computed with 3DNA (Lu and Olson, 2003), for "internal" dimer steps extracted from 145 B-DNA and 239 nonredundant protein–DNA (P + DNA) structures of 2.5 Å or better resolution from the Nucleic Acid Database (Berman *et al.*, 1992). Standard deviations are noted by the subscripted values in parentheses immediately following the corresponding averages. Values are identical for complementary steps, that is Tw(AA) = Tw(TT), and so on. Predicted data taken from Kabsch, Sander, and Trifonov (1982).

[b] B-DNA values based on 51 AG, 29 GG, 113 AA, 72 GA, 124 AT, 38 AC, 208 GC, 234 CG, 62 TA, 68 CA steps.

[c] P + DNA values based on 364 AG, 317 GG, 421 AA, 338 GA, 498 AT, 418 AC, 344 GC, 326 CG, 574 TA, 341 CA steps.

measurements (Table 11.1). Although some dimers, such as GG·CC steps, which are known to be "A-philic," are prone to undertwisting, other base-pair steps show a tendency to overtwist. Specifically, TA·TA and CA·TG dimer steps adopt very high values of Twist, coupled to a decrease in roll and an increase in slide, in many B-DNA and protein–DNA crystal structures. These preferences mimic the overwinding characteristic of synthetic polynucleotides, such as the sodium salt of the alternating poly(dAT)·poly(dAT) fiber, which forms an eightfold D-like helix rather than the A-type structures adopted under the same low-humidity conditions by mixed sequence DNA and its poly(dGC)·poly(dGC) counterpart (Davies and Baldwin, 1963; Arnott *et al.*, 1974; Leslie *et al.*, 1980). On average, the binding of proteins tends to untwist DNA (note the lower average twist values for B-DNA compared to P + DNA entries in Table 11.1).

Although the occurrences of high twist in B-DNA crystal structures have been attributed to intermolecular packing forces in the different crystal forms in which they occur and/or to the sequence context in which the dimer steps are found (Larsen, Kopka and Dickerson, 1991; Subirana and Faria, 1997), the persistence of the same extreme YR steps in protein-bound DNA structures (Suzuki and Yagi, 1995; Dickerson, 1998; Tolstorukov *et al.*, 2007) indicates that these dimers are also capable of locally overwinding the double helix and narrowing the minor groove in response to specific outside forces. The fact that DNA–DNA (Larsen, Kopka and Dickerson, 1991; Subirana and Faria, 1997) or DNA–protein contacts (Li and Olson, unpublished data) usually accompany such deformations suggests that the overtwisted C-like state is of high energy compared to standard B-DNA.

11.5
Sequence-Dependent Potentials

11.5.1
Statistical Perspective

The observed spread of DNA base-pair step parameters in high-resolution crystal structures provides one of the best available estimates of the natural, sequence-dependent deformability of the double-helical molecule (Olson *et al.*, 1998). The parameters of the 10 unique dimer steps cluster in distinctive, quasi-normal distributions consistent with harmonic behavior (Figure 11.6). The average values of the step parameters are suggestive of the rest state preferred by each dimer, and the pairwise covariance of variables, that is the differences between the mean squares and the squares of the means of all pairs of step parameters, is a measure of the intrinsic stiffness. This statistical perspective yields the smooth energy landscape that best connects the many distinct crystallographic examples and offers information about the likely overall motions of neighboring base pairs. By contrast, the thermal ellipsoids that define the range of individual atomic motions in some crystal structures (Willis and Pryor, 1975) characterize the more restricted motions of DNA within the various low-energy substates on the real "dimpled" potential landscape (Matsumoto and Olson, 2002).

The many diverse configurations of DNA seen in its complexes with different proteins constitute one of the best datasets for this sort of analysis. Since the various proteins impose different types of forces on DNA, the resulting distortions of double-helical structure are expected to cancel one another (major vs. minor groove bending, etc.), and the natural conformational response of DNA is expected to surface after averaging. By contrast, the number of "pure" DNA crystal structures, particularly those of B-DNA, is quite small and highly biased in terms of the types of available sequences and lattices in which they have been crystallized. Such constraints severely restrict the range of DNA conformational states compared to that seen in the presence of proteins.

11.5.2
Knowledge-Based Potentials

Although the equipotential contours in Figure 11.5 reflect the overall structural features of protein-bound DNA without regard to sequence, the contours superimposed on the roll–slide scatter plots in Figure 11.6 depict the distinctive

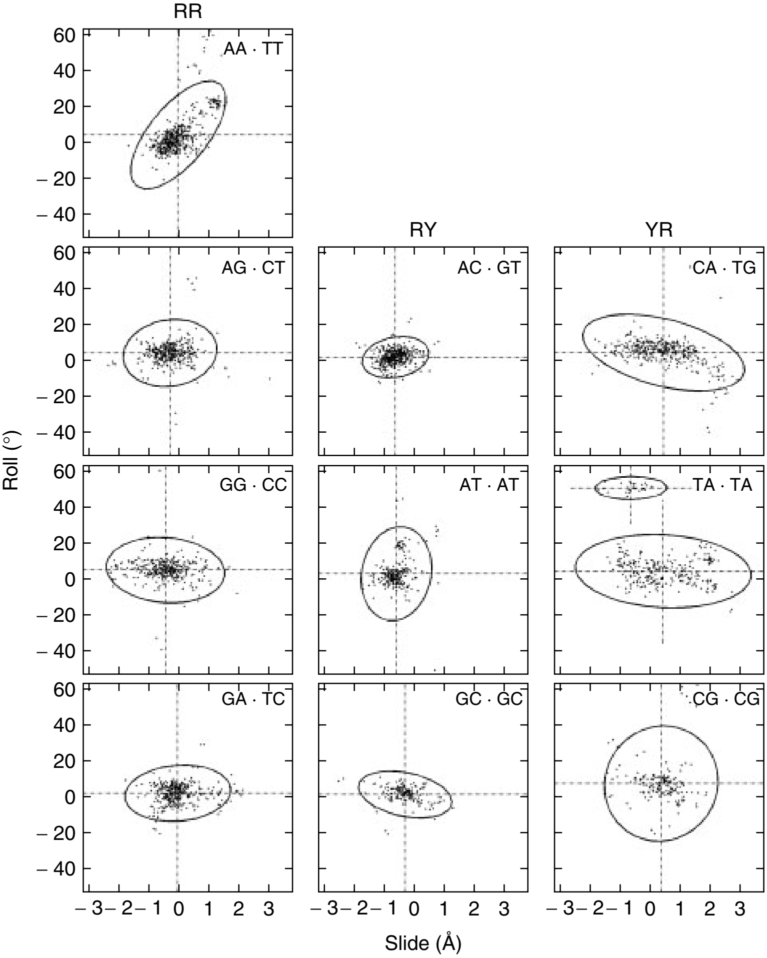

Fig. 11.6 Collective scatter plots in the roll–slide plane of base-pair step parameters found in high-resolution protein–DNA crystal complexes and derived sequence-dependent potentials of the 10 unique dimer steps. Dots correspond to the points used to derive the potentials (solid contours). Elliptical contours are projections of the multidimensional potentials on the roll–slide plane obtained from the 2 × 2 covariance matrix of observed roll–slide values. Contours correspond to deviations of parameters equal to two times the combined root-mean-square deviations of parameters. Average values of roll and slide are highlighted by dashed lines. The three columns show the respective deformational profiles of individual purine–purine (RR), purine–pyrimidine (RY), and pyrimidine–purine (YR) steps. Note the bimodal distribution of observed TA states and derived potentials in the two regimes.

deformational behavior of the 10 bp steps. As noted above, the direction of most probable change (along the long axes of the ellipses) often involves some combination of roll and slide. The extent and direction of parametric coupling depend upon sequence. For example, CA·TG dimers show a propensity to combine the negative roll that bends DNA into the minor groove with an increase in slide, whereas the AC·TG dimers tend to shear in the opposite sense with a decrease in roll.

11.5.3
Pyrimidine–Purine Deformability

The pyrimidine–purine (YR) steps stand out as the most easily deformed dimers. The intrinsic variability of the YR dimers is presumably related to their relatively weak stacking interactions (Ornstein and Fresco, 1983). Remarkably, the sharp bends in DNA observed in protein–DNA crystal complexes occur almost exclusively at YR steps (Suzuki and Yagi, 1995; Dickerson, 1998; Tolstorukov *et al.*, 2007). Moreover, the complementary base pairs remain intact in these steps. Note, in particular, the distinct bimodal character of bending (via roll) and shearing (via slide) of TA dimers. The YR steps apparently act as flexible hinges fitting the duplex to the protein surface. By contrast, the RY dimer steps are resistant to large-scale conformational distortions, serving as an indirect hindrance to DNA conformational change.

11.6
Sequence-Dependent DNA Elasticity

11.6.1
Naturally Discrete Treatment of Polymeric DNA

A coarse-grained model of DNA that makes use of the sequence-dependent dimeric potentials described herein brings new understanding of the properties of long polymers not possible with conventional elastic treatments. Incorporation of this type of model in a new theory of sequence-dependent DNA elasticity (Coleman, Olson and Swigon *et al.*, 2003; Olson, Swigon and Coleman, 2004) illustrates how the properties of "real" DNA can be misinterpreted in the context of an approximate model. For example, minicircles composed of naturally straight dimers, some of which are subject to roll–twist coupling, mimic the global response of an ideal elastic rod to imposed twisting, showing a sudden jump in the equilibrium configuration from a circle to figure of eight at a critical value of the imposed linking number. The elastic energies of such chains are smaller than the corresponding values for the ideal rod and, in some cases, show departures from ideal quadratic behavior that can be interpreted as changes in the effective elastic moduli. For example, if the coupled steps are distributed along the DNA in phase with the helical repeat, the elastic energy is nearly independent of imposed twisting, suggestive of a near-zero effective twist modulus.

Application of the sequence-dependent treatment of DNA to the loops formed by the binding of the *Escherichia coli* Lac repressor (LacR) assembly allows one to relate the fine structure of the LacR–DNA complex to a wide range of heretofore-unconnected experimental observations (Swigon, Coleman and Olson, 2006; Swigon and Olson, 2008). Examination of the 92-bp wild-type O3–O1 loop (Figure 11.7) finds antiparallel orientations of the DNA sequence on the V-shaped LacR assembly (labeled A1, A2 in the figure) to be more favorable than parallel arrangements (P1,P2). The

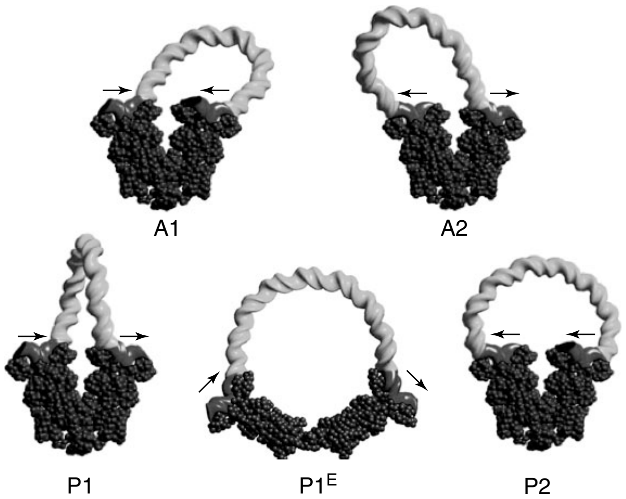

Fig. 11.7 Minimum-energy configurations of the 92-bp DNA loops formed upon binding of the Lac repressor (LacR) protein assembly to the so-called O3 and O1 operator sites on the *Escherichia coli lac* operon. DNA shown in aqua, LacR in red, and operator sites in blue. Arrows above operator sites (O3 left, O1 right) denote the orientations of DNA – antiparallel (A1, A2) and parallel (P1, P1^E, P2) – on the protein assembly. (Please find a color version of this figure on the color plates.)

free energy of one of the parallel loops (P1) is lowered substantially when the V-shaped structure is allowed to open ~80° (P1^E), falling close to or below the values computed for the antiparallel loops, depending upon the estimated cost of protein deformation. One of the antiparallel loops (A1) has the DNA fine structure consistent with the $KMnO_4$ sensitivity of the native loop (Borowiec *et al.*, 1987), that is localized overtwisting and exposure of the major-groove atoms in the hypersensitive TTTAT base-pair stretch ~37 bp upstream of (preceding) the O1 site (highlighted in blue on the right side of the protein assemblies illustrated in Figure 11.7). The capability to draw such connections with the chemical literature highlights one of the clear advantages of a sequence-dependent approach over more simplified models currently used in the interpretation of DNA looping

11.6.2
Intrinsic Motions of "Real" DNA Sequences

A new computational approach for studying the dynamic properties of relatively long DNA molecules also keeps track of the local sequence-dependent features of the double helix (Matsumoto and Olson, 2002; Matsumoto, Tobias and Olson, 2005a, 2005b). The description of the collective motions of DNA in terms of base-pair steps builds upon general formulations developed by others to express the normal modes of proteins in terms of internal chemical coordinates (Noguti and Go, 1983;

Braun, Yoshioki and Go, 1984; Higo, Seno and Go, 1985). Although normal-mode analysis has been previously used to study DNA dynamics, it is only now possible, with a base-pair-level perspective, to examine the vibrations of longer pieces of DNA. Apparent mechanical constants, which describe the overall elastic behavior of linear DNA, can be obtained by substituting the computed normal-mode frequencies in classical expressions for the normal modes of an ideal elastic rod (Strutt (Baron Rayleigh), 1945). The calculations show how the natural coupling of local conformational variables affects the global motions of DNA. For example, successful correspondence of the computed stretching modulus with experimental data requires that the DNA base pairs be inclined with respect to the direction of stretching or reoriented upon forced extension (Matsumoto and Olson, 2002). Chain extension is thereby effected by low-energy transverse motions that vary the overlap but preserve the strong van der Waals' stacking of neighboring base-pair planes. The computed stretching constant significantly exceeds observed values if the DNA is pulled in a direction perpendicular to the base-pair planes.

End-to-end constraints placed on a naturally straight DNA molecule, in combination with natural conformational features of the double helix, also account for the substantially larger torsional moduli determined with state-of-the-art, single-molecule experiments (Bryant *et al.*, 2003; Gore *et al.*, 2006) compared to values extracted from solution measurements. The computed normal-mode frequencies and torsional moduli increase substantially if base pairs are inclined with respect to the double-helical axis and the deformations of selected conformational variables follow known interdependent patterns (Matsumoto and Olson, 2006). The changes are greatest if the fluctuations in dimeric twisting are coupled to parameters such as roll, slide, and rise, which directly alter the end-to-end displacement. Imposed restraints that mimic the end-to-end conditions of single-molecule experiments then impede the twisting of base pairs and increase the torsional modulus. Thus, the twisting motions of DNA are predicted to be strongly coupled to other motions, such as global bending and stretching, in which the end-to-end distance of the DNA changes. Indeed, new single-molecule studies (Lionnet *et al.*, 2006; Gore *et al.*, 2006) show that DNA twisting and stretching are coupled at the macromolecular level in the same sense as the high-resolution structural information used in the knowledge-based potentials. That is, when stretched, the double helix overwinds and when compressed, it unwinds.

11.6.3
Sequence-Dependent Effects in Monte-Carlo Simulations of Short DNA

A new, computationally efficient Monte-Carlo technique (Czapla, Swigon and Olson, 2006) provides estimates of the ring-closure properties of short, realistically modeled DNA chains. The method has been used to investigate the cyclization properties of arbitrary-length DNA with greatly enhanced sampling sizes, that is $O(10^{14})$ configurations, and to estimate J factors lower than 0.1 pM with high accuracy. The methodology was checked against classic theoretical predictions of the cyclization properties of an ideal, inextensible, naturally straight, DNA elastic rod (Shimada and

Yamakawa, 1984) and then applied to investigate the extent to which one can account for the unexpectedly large *J* factors of short DNA chains without the need to invoke significant distortions of double-helical structure. Several well-known structural features of DNA – including the presence of intrinsic curvature, roll–twist coupling, or enhanced pyrimidine–purine deformability – bring the computed *J* factors in line with the observed data. Moreover, periodically distributed roll–twist coupling reduces the magnitude of oscillations in *J*, seen in plots of *J* versus chain length, to the extent found experimentally. Thus, in contrast to earlier suggestions (Yan and Marko, 2004; Cloutier and Widom, 2005; Du *et al.*, 2005; Wiggins, Phillips and Nelson, 2005), it is not necessary to melt, kink, or freely twist the DNA double helix to bring the computed *J* factors in line with the enhanced cyclization propensities of molecules much shorter than the persistence length (Cloutier and Widom, 2004, 2005).

Acknowledgments

The US Public Health Service under research grants GM20861 and GM34809 and instrumentation grant RR022375 has generously supported this work. AVC gratefully acknowledges traineeship support from the US Public Health Service (training grant GM08319) and fellowship support from the Program in Mathematics and Molecular Biology (Burroughs–Wellcome Fund Interfaces Program) and DS research support from an A.P. Sloan Fellowship and NSF grant DMS-05-16646. We also thank Mr Mauricio Esguerra Neira for assistance with the preparation of figures.

Glossary

A-philicity: the tendency of a DNA sequence to adopt A-like helical structures (Ivanov and Minchenkova, 1995).

Linking number: a topological measure of the number of times the two strands of a cyclic DNA molecule are interlinked (White, 1989).

Nucleosome core particle: the basic packaging unit of DNA in eukaryotic cells, that is cells with nuclei, containing ~147 bp wrapped ~1.6 left-handed superhelical turns around a core of eight histone proteins.

Poisson ratio: the negative of the ratio of radial compression to axial elongation of an elastic rod (Landau and Lifshitz, 1986).

Purine: a heterocyclic organic molecule constituted of fused six- and five-membered rings that makes up one of the two groups of nitrogeneous bases in DNA. The two purines, adenine (A) and guanine (G), form hydrogen-bonded complexes with the complementary pyrimidines, thymine (T) and cytosine (C).

Pyrimidine: a six-membered heterocyclic organic molecule with nitrogen atoms at the 1 and 3 positions of the ring that makes up one of the two groups of nitrogeneous bases in DNA. See *Purine*.

Superhelix: a higher-order molecular structure formed by regularly spaced distortions of a helix, such as the wrapping of double-helical DNA around the histone proteins in the nucleosome core particle.

Unique dimers: the 10 DNA base-pair steps with unique sequence and structural identities, four of which are self-complementary, with the same sequence in each strand (AT·AT, CG·CG, GC·GC, TA·TA), and six of which are non-self-complementary (AA·TT, AG·CT, GG·CC, GA·TG, AC·GT, CA·TG).

12.1
Introduction

Biomembranes fulfill multiple functions in living cells, such as compartimentalization, formation of permeability barriers, regulation of transport, and service as platform for numerous biochemical activities. The molecules that enable this variability in functions are lipids. Driven by the hydrophobic effect, lipids spontaneously self-assemble into a variety of ordered structures in which the lipid headgroups cooperatively shield the hydrocarbon tails from the unfavorable exposure to the aqueous environment. The planar lipid bilayer is just one such structure; among a plethora of other aggregation geometries are spherical- and rod-like micelles, as well as inverse and bicontinous phases.

Fluid lipid bilayers are soft materials with remarkable physical properties that include the ability to change their shape and topological structure. Contained in the latter is membrane rupture (which leads to the formation of a pore), membrane fusion–loosely defined as the merger of two lipid bilayers into a single one–and fission (the inverse of fusion). Hence, membrane fusion is already integrated into the design of the biomembrane's basic building blocks. It is therefore plausible that the fusion of *bare* bilayers has been studied intensively in the past (Section 12.2). Initially, some focus in these studies was put on understanding the fusion between highly charged vesicles induced by divalent cations, especially calcium (Ca^{2+}). Here, a complex set of interactions leads to the attraction of like-charged vesicles followed by a large-scale aggregation and condensation of the apposed membranes (Arnold, 1995). This contrasts other more localized fusion pathways in bare membranes and also in biological systems where the two membranes are brought together and become finally merged by a specialized fusion machinery.

Two closely apposed lipid vesicles (and more generally, any two membrane-enclosed aqueous compartments) need not necessarily fuse with each other; fusion is just one out of several possible outcomes. Depending on a variety of different factors the vesicles may remain aggregated, undergo only part of the fusion reaction, or rupture. The latter case may eventually lead to the formation of a single vesicle but it is accompanied by leakage. A definition of membrane fusion that excludes this alternative scenario has been stated by Lentz (2007): Membrane fusion is characterized by

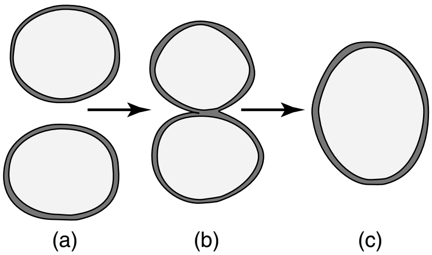

Fig. 12.1 Fusion of two lipid vesicles: (a) Prior to fusion, the two vesicles are separated; (b) The fusion process is generally thought to proceed through intermediate states such as the merger of only the proximal monolayers followed by the formation of a fusion pore; (c) Finally, after fusion is completed, only one single vesicle remains. Both lipids and contents of the initially two vesicles are mixed in the final state, and little leakage has occurred.

"mixing of entrapped content between two membrane-enclosed aqueous compartments accompanied by mixing of membrane components (lipids and likely proteins) but with little accompanying leakage of entrapped contents." The fusion of two vesicles according to this definition is illustrated in Figure 12.1.

Topological changes that are reminiscent of membrane fusion also occur in structural membrane transitions of lipid bilayers, particularly in the transition from the planar bilayer to the inverse hexagonal phase (the $L_\alpha \rightarrow H_{II}$ transition) and to inverse cubic phases (the $L_\alpha \rightarrow Q_{II}$ transition). Both the planar phase (L_α) and the inverse hexagonal phase (H_{II}) are illustrated in Figure 12.4 (Section 12.2.4). The forces that drive the transition result from a change of the preferred aggregation geometry of the involved lipids (here too see Section 12.2.4). At least in some cases, the transition involves the formation of an intermediate structure–a so-called stalk–that very likely also appears during fusion of model and perhaps even biological membranes (Chernomordik, Zimmerberg and Kozlov, 2006). Studying structural phase transitions (Section 12.2.1) therefore also contributes to the understanding of membrane fusion.

That fusion proceeds through the formation of a stalk intermediate has been suggested early (Kozlov and Markin, 1983). The stalk hypothesis has since then become a central paradigm of membrane fusion. A large number of experimental results can be explained based on a stalk-involving fusion pathway. This includes the way in which nonlamellar phase-forming lipids promote or inhibit fusion (Section 12.2.4). Other fusion promoters, such as fusogenic peptides, are less easily understood. Indeed, the ability of certain peptides to promote fusion appears to depend sensitivity on their amino acid structure, often with no simple correlation between structure and mechanism of action. Generally, stalk formation and subsequent opening of the fusion pore have attracted considerable modeling efforts, based on elasticity theory (Section 12.5.4) and computer simulations (Section 12.6).

Biological fusion is vital for a multitude of functions–fertilization, formation of multinuclear cells in development, intracellular membrane trafficking and recycling, exocytosis, and infections caused by enveloped viruses–all require the merger of two biomembranes. Biological fusion is catalyzed by special proteins. The best-studied cases are viral fusion proteins (and here especially the fusion protein hemagglutinin (HA) of the influenza virus; see Section 12.3.3) and the synaptic vesicle fusion machinery (centered around SNARE complexes;

Section 12.4.1). Yet many other systems are being studied intensively as well, among them class II viral fusion proteins (Section 12.3.2) and cell–cell fusion (Section 12.4.2). A central question is whether–despite large differences in the structure of different fusion proteins–there are common fusion mechanisms, such as the formation of a stalk intermediate. Related is to what extent biological fusion is lipid or protein based (Mayer, 2001). In other words, do fusion proteins merely lower the energy barriers to the fused state or do they create an entirely new fusion path that does not exist for bare membranes?

12.2
Bilayer Fusion

This section is concerned with the fusion of membranes in the absence of fusion-proteins. When vesicles in aqueous solution approach each other by means of thermal motion or by an external field, a repulsive force between the respective bilayers acts to prevent close contact. The net interbilayer force can be decomposed into electrostatic forces, undulation forces, and hydration forces (Section 12.5.1). Particularly the latter ones, which represent structural forces due to the ordering of solvent molecules close to the membrane interfaces, become very strong at short distances. Vesicle aggregation can nevertheless be induced through divalent cations for like-charged membranes (Section 12.2.2), through polymers (Section 12.2.3), or by using oppositely charged membranes (Section 12.2.6). These aggregation methods prime for fusion but do not intrinsically induce it. That is, the membranes may reside in an aggregated state for a long time period. For example, large concentrations of sodium (of about 0.5M) induce aggregation but not fusion of sonicated phosphatidylserine (PS) vesicles (Day *et al.*, 1980). Needed for fusion is an additional destabilization (i.e. stress) of the planar lipid bilayer. In bare lipid bilayers, stress occurs as *curvature stress* or *lateral tension.* They express deviations of the curvature and lateral area, respectively, of a lipid layer from the preferred values.

Fusion is generally believed to proceed through intermediate states. The presence of intermediates reflects local minima in the energy landscape of the fusion path. One of the most frequently discussed fusion pathways–based on the stalk-pore model (Kozlov and Markin, 1983)–is shown in Figure 12.2. It starts from two closely apposed membranes (a), evokes the formation of a *stalk* (b) which then widens into a *transmembrane contact* (c). Further, radial expansion gives rise to an extended *hemifusion diaphragm* which ruptures (e) into a *fusion pore* (f).

12.2.1
Lamellar-to-Inverted Phase Transitions

Inverted lipid phases include the inverse hexagonal phase (H_{II} phase) and various bicontinous cubic phases (Q_{II} phase) (Seddon *et al.*, 2000). The inverse hexagonal phase (H_{II} phase) consists of long rod-like inverted micelles that are parallel and closely packed into an hexagonal array. Cubic phases lack the translational symmetry of the inverse hexagonal phase; they form a network of inverted micellar tubes that has cubic symmetry. The packing geometry in the Q_{II} phases is generally more *inverted cone*-like (Section 12.2.4) than

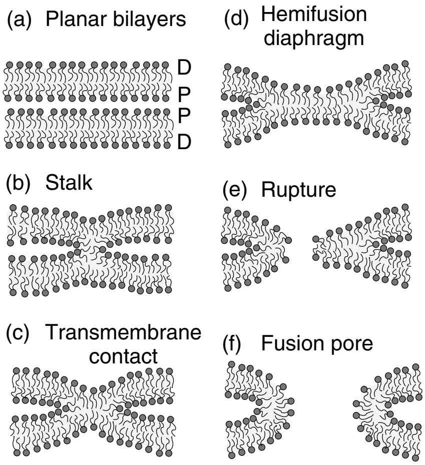

Fig. 12.2 The fusion pathway according to the stalk-pore model. Two closely apposed planar membranes (a) connect their proximal monolayers through a *stalk* (b) which widens into a *transmembrane contact* (c). A fusion pore (f) may form already at this point or after radial expansion into an extended *hemifusion diaphragm* (d) and subsequent rupture (e). All diagrams show two-dimensional schematic illustrations of three-dimensional systems. The lipid headgroups are represented by dark circles, lipid tails comprise the hydrocarbon region as indicated. The proximal and distal monolayers of the planar bilayers in diagram (a) are marked by the letters "P" and "D", respectively.

in the H_{II} phase. Lipids with small, weakly hydrated headgroups or with a bulky hydrocarbon core are expected to form such structures. Lamellar-to-inverted phase transitions can be triggered by increasing the temperature or by changing the hydration level (Gawrisch *et al.*, 1992). A typical example is dioleoylphosphatidylethanolamine (DOPE) with a transition temperature of 3 °C in excess water (Toombes *et al.*, 2002). Increase in temperature disorders the hydrocarbon chain region to a larger extent than the headgroup region, thus shifting the preferred packing geometry toward more inverted cone-like.

Transitions between lamellar and inverted phases, especially involving the inverse hexagonal phase, have been studied intensively in the past, partly because of their possible relevance for membrane fusion. A central objective is the identification of intermediate structures between the L_α and H_{II} phases, making them candidates to appear as fusion intermediates as well. Experimental observations, based on techniques such as X-ray diffraction, spectroscopy, freeze-fracture and cryo-electron microscopy, support a number of distinct intermediates.

12.2.1.1 Lipidic Intramembraneous Particles

Early observations based mainly on freeze-fracture microscopy revealed so-called lipidic intramembraneous particles which are spatially localized, typically string-like, defects, interpreted as either (a) inverted micelles sandwiched between the two leafs of a single bilayer (Verkleij *et al.*, 1979) (illustrated in Figure 12.3a) or two bilayers (Figure 12.3b) or (b) intermembrane attachment sites (Hui and Stewart, 1981). Note that the latter interpretation corresponds closely to the modern terminology of stalk-like intermediates. Theoretical analysis suggests that the structure in Figure 12.3a has generally larger energy than that in Figure 12.3b Siegel (1984).

12.2.1.2 Extended Lipid Conformations

The so-called extended lipid conformation refers to lipids that have their

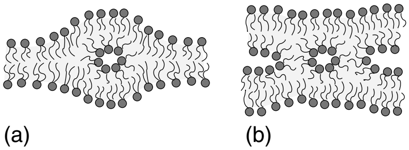

Fig. 12.3 "Lipidic intramembraneous particles" were among the first structures suggested as intermediates in the $L_\alpha \rightarrow H_{II}$ transition. The illustration shows a single inverted micelle (which can be spherical or tubular) sandwiched between a single bilayer (a) or between two bilayers (b). Note that a structure similar to (b) was recently suggested to be involved in the growth mechanism of the tubular rods in the H_{II} phase (Rappolt *et al.*, 2003).

two hydrocarbon chains reside in the proximal monolayers of two adjacent membranes. Instead of an essentially parallel chain alignment, these lipids reside in an extended conformation with the two hydrocarbon tails pointing in opposite directions. Such an arrangement is prohibited in a single bilayer by the hydrophobic effect but has been suggested (Kinnunen and Holopainen, 2000) to relieve packing stress for two apposed membranes that are about to undergo the transition to an inverted phase. The actual transition is triggered by the extended lipids in a "zipper"-like mechanism. Support for this hypothesis derives mainly from nuclear magnetic resonance (NMR) and fluorescence spectroscopy.

12.2.1.3 **Direct Formation of Inverted Tubular Micelles**

X-ray scattering-based structure reconstitution of multilamellar palmitoylphosphatidylethanolamine (POPE) vesicles within the region of L_α/H_{II} phase coexistence suggests a model of cooperative formation of inverted tubular micelles sandwiched within the multilamellar bilayer stack (Rappolt *et al.*, 2003). Since the thickness of the free water layer between adjacent membranes was found to be very small (less than 1 nm) the inverted tubular micelles are suggested to form directly from two proximal monolayers without having to pass through an intermediate. The model is structurally related to that of inverted micelles sandwiched between two bilayers (Figure 12.3b).

12.2.1.4 **Stalks**

A stalk is a lipid connection between the proximal monolayers of two fusing bilayers (Figure 12.2b). Note that the distal monolayers have not established direct contact between their hydrocarbon chain regions. The formation of a stalk occurring as an intermediate during either a structural phase transition between the lamellar and an inverted phase or during a fusion reaction was first suggested as a hypothesis (Kozlov and Markin, 1983), but has subsequently gained experimental support. Evidence derives mainly from cryo-electron microscopy (Siegel and Epand, 1997) and X-ray scattering (Yang and Huang, 2002). The latter showed that stalks can form as an equilibrium structure for several different lipid systems at room temperature and low hydration. Structure reconstitution through X-ray scattering on a membrane stack was possible because the stalks between any two membranes arranged into an hexagonal lattice. A similar structure was also observed to form in a coarse-grained molecular dynamics (MD) simulation (Marrink and Mark, 2004).

12.2.1.5 Transmonolayer Contact and Interlamellar Attachment

Pathways of structural transitions involving stalks must branch at some point depending on whether the transition proceeds to H_{II}- or Q_{II} phase. Models for both scenarios have been developed (Siegel, 1999; Siegel, 1993). Stalks are suggested to evolve into transmonolayer contacts (TMCs)–illustrated in Figure 12.2c–in which the hydrocarbon chains of the distal monolayers start contacting each other. The H_{II} phase could then form upon elongation of TMCs followed by an aggregation. On the other hand, immediate opening of a TMC creates a pore, the so-called interlamellar attachment (ILA). Lattice formation of ILAs would then lead to the Q_{II} phase.

12.2.2
Divalent Cations

A number of biologically important lipids such as PS, phosphatidyglycerol (PG), and phosphatidic acid (PA) are anionic. Vesicles that contain large fractions of these charged lipids can be fused by adding divalent cations such as Ca^{2+} or Mg^{2+}. The threshold concentration required to induce fusion is in the millimolar range (Arnold, 1995) and is generally lower for Ca^{2+} than for Mg^{2+}. For example, Ca^{2+} is able to fuse both large and small unilamellar PS vesicles, whereas Mg^{2+} is unable to fuse large unilamellar PS vesicles but mediates aggregation. Monovalent cations such as Na^+ and K^+ (with the exception of H^+) are able to induce vesicle aggregation but usually not fusion. Generally, the ability of a given cation to induce aggregation is distinct and well separated from its ability to induce fusion. Both processes are separate and superimposable. For example, Mg^{2+} enhances the rate of Ca^{2+}-mediated fusion in large unilamellar PS vesicles through its ability to preaggregate the vesicles (Wilschut, Düzgüne and Papahadjopoulos, 1981)

No nonlamellar phase-forming lipids are needed for divalent ion-mediated fusion. Hence, the fusion mechanism does not likely involve the formation of a stalk intermediate. Instead, the two apposed membranes form a highly condensed, dehydrated complex in which the cation bridges and rigidifies the two adhering membranes. The condensed complex would tend to maximize its contact area thus exerting a large bending moment and tension onto the remaining (not aggregated) vesicle parts, particularly at the rim region. It is plausible that this leads to either membrane rupture or fusion, but the detailed molecular mechanism is unclear at present. A conceptual model that captures this scenario is the adhesion–condensation mechanism (Kozlov and Markin, 1984).

Cytosolic calcium concentration is usually about 100 nM, whereas external calcium is present in the millimolar range. Intracellular calcium concentrations are tightly regulated as this ion is involved in numerous signaling processes. For example, in secretory cells, calcium enters into the cytosol with micromolar concentrations from both the extracellular space and internal stores located in the endoplasmatic reticulum (ER). Due to the generally low concentrations, and also due to the fairly low charge densities of biological membranes, it may not seem likely that calcium is involved directly in the fusion of sectretory vesicles with the negatively charged plasma membrane.

12.2.3
Polymer-Induced Fusion

Water-soluble polymers are able to promote the fusion of lipid vesicles. A convenient polymer is polyethylene glycol (PEG) which has been studied most extensively. The role of the polymer is to induce a depletion attraction between vesicles (Section 12.5.1). The method is often used as an auxiliary tool to enhance fusion rates of membranes that are already primed for fusion. For example, the presence of PEG reduces the concentration of calcium needed to trigger the fusion between anionic vesicles (Ohki and Arnold, 1990). Another example is small unilamellar vesicles (SUVs) whose curvature stress can be relieved by fusing them into larger vesicles. As has been pointed out, the use of SUVs could affect the fusion mechanism as compared to large vesicles because they limit the size of possible fusion intermediates and require trans-monolayer redistribution of lipids (Siegel, 2004).

PEG-induced fusion has been employed to investigate the dynamics of the fusion process. One of the key studies (Lee and Lentz, 1997) lead to the identification of a sequence of steps for the particular system of 45 nm large vesicles consisting of a mixture of dioleoylphosphatidylcholine (DOPC) and dilinolenoylphosphatidylcholine of composition 85/15 mol/mol. The steps involve two intermediates that are consistent with stalk formation (Figure 12.2b) followed by transmonolayer contact (TMC, Figure 12.2c). Kinetic modeling of this system predicted activation energies of about 60 k_BT to reach the first intermediate from an initially aggregated state, 50 k_BT for the second intermediate, and 36 k_BT for the final fusion pore. (Here k_BT is the thermal energy with k_B being Boltzmann's constant and T the absolute temperature.) The subsequent analysis for other systems lead to a generalized model (Weinreb and Lentz, 2007) for PEG-induced fusion as a two-state sequential process with the two intermediates accounting in a general sense for an ensemble of structures related to stalks and TMCs. PEG has been used extensively in the past to study the fusion of bare membranes but, of course, it is equally valuable to study how proteins promote fusion (Lentz *et al.*, 2000).

12.2.4
Lipids as Fusion Modulators

Bilayer stability can be characterized on a qualitative level in terms of the *effective shape* of lipid molecules (Israelachvili, 1992). This shape is dynamic, it results from an averaging over many ($\approx 10^{10}$ s^{-1}) different conformations of the flexible hydrocarbon tails.

The geometry of planar bilayers indicates a preferential *cylinder-like* shape of the lipid molecules. Canonical example of a bilayer-forming lipid is phosphatidylcholine (PC), but others such as the anionic lipids phosphatidylglycerol (PG) and PS form as well stable bilayers at physiological conditions. Lipids with preferred *conical* shape such as the single-tailed lyso-phosphatidylcholine tend to aggregate into spherical or cylindrical micelles. Correspondingly, the preferred shape of an *inverted cone* implies formation of inverted phases. For example, phosphatidylethanolamine (PE) typically forms the inverse hexagonal

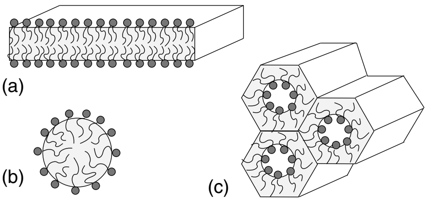

Fig. 12.4 Schematic illustration of three basic aggregation geometries: (a) planar bilayer (L_α); (b) spherical or cylindrical micelle; (c) inverse hexagonal phase (H_{II}). The corresponding effective shape of the lipids in these aggregates is cylindrical, conical, and inverse conical respectively.

phase. Figure 12.4 schematically illustrates three basic aggregation geometries. Note that the effective shape of a lipid species depends also on external conditions (such as temperature, level of hydration, pH, and salt content). For example, lowering the temperature induces the $H_{II} \rightarrow L_\alpha$ transition in DOPE. Upon also lowering the level of hydration, a transition back to the L_α phase may occur (Gawrisch *et al.*, 1992). Note also that a quantitative measure of the propensity to adopt curved aggregation geometries is provided by elasticity theory. As outlined in Section 12.5.2, monolayers composed of cone-like (inverted cone-like) lipids imply a positive (negative) *spontaneous curvature*; see Eq. (1).

Generally, lipids that favor inverse phases also facilitate fusion. PE is a well-studied example of such "fusogenic" lipids (Cullis and de Kruijff, 1978). The PE headgroup is sterically small; compared to PC it lacks three methyl groups. Beyond that, it forms an intermolecular hydrogen bond network which is accompanied by a low level of hydration, thus reducing the hydration repulsion (Section 12.5.1) between apposed bilayers.

If the fusion path involves highly curved intermediates, it can be expected that small concentrations of lipids that form nonlamellar phases affect the propensity to undergo fusion. Thus, if the preferred molecular shape of the added nonlamellar lipids fits that of the intermediate, fusion (or, at least, the rate of adopting the intermediate state) will be facilitated. Based on this notion, experiments can be designed to probe putative intermediate structures. For example, the stalk-pore model (Figure 12.2) predicts that stalk formation is promoted (inhibited) by inserting inverted cone-like (cone-like) lipids into the proximal monolayers. In other words, a negative spontaneous curvature of the proximal monolayers supports stalk formation. Conversely, opening of the fusion pore is predicted to be facilitated by a positive spontaneous curvature of the distal monolayers. This opposite influence of nonlamellar lipids on different stages of fusion, depending on whether they are present in the proximal or distal monolayers, is indeed observed experimentally (Chernomordik *et al.*, 1995).

Diacylglycerol (DAG) is a lipid of some interest because it modulates the physical properties of the host membrane and also acts as a second messenger-signaling lipid. More specifically, upon activation, the membrane-bound enzyme phospholipase C splits the lipid phosphatidyl inositol-bisphosphate (PIP_2) into its water- soluble headgroup inositol triphosphate (IP3) and DAG. The headgroup-lacking lipid remains in the membrane where it could subsequently act as a fusion promotor through its strongly inverted cone-like shape. Support comes from model membranes where the production of DAG by phospholipase C triggers fusion in a manner that correlates with the formation of cubic phase intermediates (Goñi and Alonso, 1999).

12.2.5
Peptides as Fusion Modulators

Naturally occurring and synthetic peptides as well as protein fragments are widely studied in terms of their ability to destabilize lipid bilayers and to induce structural changes. For example, antimicrobial peptides, used by many animals as host defense systems, trigger pore formation or solubilize their target membrane (Bechinger and Lohner, 2006). Sometimes, peptides leave the bilayer structure intact but tubulate the shape of the membrane. In other cases, transmembrane peptides, both natural (such as gramicidin A) and synthetic, are able to induce structural transitions from a planar lipid bilayer to inverse nonlamellar phases. Among the most remarkable examples is the synthetic peptide WALP (acetyl-GWW(LA)$_n$ WWA-ethanolamide with $n = 5-10$) which induces the H_{II} phase in a PC membrane, given the so-called hydrophobic mismatch between membrane and peptide is sufficiently large (Killian, 1998). Intermediate structures for transmembrane peptide–lipid systems during the $L_\alpha \rightarrow H_{II}$ phase transition are not known.

Viral fusion peptides have evolved to trigger fusion. Not surprisingly, some of these peptides are also able to induce inverse nonlamellar phases (Epand, 1997). Yet, the mechanism by which viral fusion peptides destabilize their target membrane during viral fusion is not well understood. One possibility is softening of the host membrane in order to decrease the energy to form fusion intermediates (Tristram-Nagle and Nagle, 2007). On the basis of molecular modeling it has been suggested that oblique orientations of fusion peptides in the membrane are crucial for their function (Peuvot *et al.*, 1999). Most detailed experimental evidence is available for the fusion peptides of the influenza and immunodeficiency viruses. The structure of both peptides as determined by NMR in micelles (Tamm, Lai and Li, 2007) is shown in Figure 12.5. In the latter case, the helix is straight and very likely oblique in the membrane. Yet, the fusion peptide of HA (the fusion protein of influenza virus) consists of two α-helical segments linked by a rigid kink region. The peptide thus forms a boomerang-like shape with both its arms being tilted with respect to the membrane interface (Tamm, Lai and Li, 2007). Boomerang-like insertion has also been found for the fusogenic peptide sequence B18 from the sea urchin fertilization protein bindin (Afonin *et al.*, 2004) which could indicate a general structural motif for fusogenic peptides.

12.2.6
Oppositely Charged Membranes

The repulsion between two apposed bilayers can also be overcome electrostatically by using oppositely charged membranes. Indeed, oppositely charged giant unilamellar vesicles (GUVs) spontaneously adhere onto each other and subsequently may undergo hemifusion or full fusion as evidenced by fluorescence video microscopy (Pantazatos, Pantazatos and MacDonald, 2003). Owing to the mutual neutralization of oppositely charged lipids, the two apposed membranes condense

onto each other which makes the adhesion–condensation mechanism (Kozlov and Markin, 1984) likely to describe the fusion process, similarly to the fusion induced by divalent cations. For highly charged GUVs, membrane rupture and engulfment of smaller by larger vesicles are other possible outcomes. Engulfment becomes especially frequent if GUVs contain some lipids with covalently attached PEG (Lei and Macdonald, 2008). On the other hand, cholesterol stabilizes the hemifused state (García *et al.*, 2001).

Fusion of oppositely charged membranes is unlikely to be directly relevant for living cells because of the absence of cationic lipids. However, cationic lipids are being used in gene therapy as nonviral delivery systems for DNA. They spontaneously form complexes (so-called lipoplexes) with negatively charged DNA that are able to enter their target cells and release the DNA into the cytoplasm. The advantages over viral vectors have stimulated intensive research to improve transfection efficiency. Many different cationic lipids have been synthesized and tested so far but conclusive correlations between biophysical properties of lipoplexes and transfection efficiency is still lacking. However, it has been realized early that the use of fusogenic lipids such as PE as the so-called helper lipid often enhances transfection efficiency (Hope *et al.*, 1998). Two of the crucial steps in the delivery pathway are the entry of the lipoplex into the cytoplasm and the release of the DNA. Some evidence exists of lipoplexes being internalized into cells via the endocytotic pathway. To what extent the escape from the endosome and possibly also the release of DNA from the lipoplexes involve fusion remains to be established (Zuhorn, Engberts, and Hoekstra, 2007).

12.3
Viral Fusion

Viral fusion is the best studied case of exoplasmatic fusion. Relevant with respect to the process of membrane fusion are enveloped viruses. These viruses have their nucleocapsid enclosed in a lipid bilayer membrane that the virus acquires from a host's cell membrane during virus budding. Delivery of the nucleocapsid cargo into the cytoplasm of a new host cell requires fusion of the viral membrane with that of the host cell. An exception is the virus-triggered formation of syncytia (multinuclear cells) that allows the direct passage of viral material from cell to cell.

Nonenveloped viruses do not possess a lipid membrane and thus have to use alternative strategies to translocate their genome into the host cell. These strategies are often not well understood but they include breaking the hydrophobic membrane barrier through the formation of membrane pores–this is the entry path of polioviruses–or directly through membrane rupture. For example, adenoviruses, which have potential applications as viral transport vehicles of genetic material in gene therapy, become internalized into endosomes where they initiate membrane rupture.

Enveloped viruses bind to the target membrane through specific interactions of viral proteins with individual or multiple cell membrane receptors. Nonspecific interactions, especially electrostatic attraction between membrane-associated glycosaminoglycans and ionizable groups of certain viruses, may contribute to the initial recognition of a potential target cell (Sieczkarski and Whittaker, 2004). Membrane receptors include members of the immunoglobulin family, the chemokine receptor family, the low-density lipoprotein receptor family, integrins, or specific carbohydrate groups such as sialic acid. Enveloped viruses have their receptor binding sites located on spike-like glycoproteins. A single virus contains many (often hundreds) of these proteins that can make a multitude of contacts with their corresponding receptors. Thus, even if the binding energy to an individual receptor is weak, the sum of all binding contacts amounts to a large binding energy, much larger than the thermal energy k_BT. It is no surprise that some viruses such as influenza virus and paramyxovirus are in need of special receptor-destroying enzymes (so-called neuroaminidases) that release the virus in case of unproductive binding.

The fusion process of enveloped viruses can take place either directly at the plasma membrane or, for the majority of enveloped viruses, after internalization via the endocytotic pathway (Section 12.3.1). In the former case, direct fusion with the plasma membrane, the viruses need not be exposed to a mildly acidic environment. Instead, fusion proceeds at neutral pH. Examples include most retroviruses, paramyxoviruses, herpesviruses, poxviruses, and coronaviruses. Upon direct entry into the cell through the plasma membrane, the nucleocapsid is released into the cytoplasm from where it is transported to the appropriate transcription or translation sites via the cytoskeletal transport machinery.

12.3.1
Internalization through Endocytosis

Most enveloped viruses become internalized into the cell through endocytosis. These include the orthomyxoviruses, togaviruseses, rhabdoviruses, flaviviruses, and bunyaviruses. Of the two endocytotic trafficking pathways, receptor-mediated endocytosis and bulk-phase endocytosis, the former one appears to be most relevant for virus internalization. To what extent bulk-phase endocytosis–the unspecific mechanism of internalization (pinocytosis)–contributes to viral infections is not well known. Receptor-mediated endocytosis is based on the specific, high-affinity interaction of the virus with cell membrane receptors that trigger endocytosis. The major route of receptor-mediated endocytosis is through clathrin-coated pits. Clathrin is the building block of coated vesicles. It has a tendency to self-assemble on the plasma membrane into a curved cage that invaginates the bilayer and eventually pinches off forming a coated vesicle. A significant protein in this process is dynamin (a guanosine triphosphate (GTP)-binding protein) which may act as a force-generating molecule driving the coated vesicles to pinch-off. Members from the nonenveloped virus families of picornaviruses and polyomaviruses appear not to have to rely on the presence of clathrin. Instead, they are able to interact with lipid rafts or caveolae to become internalized (Sieczkarski and Whittaker, 2004).

Using an endocytotic vesicle as a transport vehicle allows the virus to pass beyond the cytoskeletal cortex (which is typically most dense beneath the cell membrane) and to reach a location closer to the nucleus. Endocytic vesicles are transported to and then fuse with early endosomes. Being located in the endosome, the virus is still separated by the endosomal membrane from the cytosol. Yet, in the endosome, the virus encounters a mildly acidic environment which initiates the fusion reaction between the viral and endosomal membranes.

12.3.2
Viral Fusion Proteins

Enveloped viruses generally possess specialized proteins–type I membrane glycoproteins–that mediate the fusion process and are therefore referred to as *fusion proteins* (Teissier and Pecheur, 2007). Fusion proteins have a large ectodomain in order to interact with the target membrane. They become proteolytically cleaved by proteases of their initial host cell, but the subunits remain associated. Fusion proteins often oligomerize. Despite significant differences between fusion proteins, they all contain a transmembrane domain and a fusion peptide, the latter being a highly conserved short hydrophobic sequence of about 10–12 amino acid residues that is thought to play a central role in the destabilization of the target membrane. Prior to the fusion reaction, the fusion peptides are buried within the aggregates of the fusion proteins. Fusion is initiated by receptor binding (for viruses that enter directly through the plasma membrane) or by the low pH encountered in the endosome (for viruses that are internalized through endocytosis). In both cases, the fusion proteins undergo drastic conformational changes that ultimately lead to the cooperative insertion of several fusion peptides into the target cell.

On a structural level, fusion proteins can be divided into at least two major classes: class I fusion proteins and class II fusion proteins. Class I fusion proteins have large α-helical content and form spike-like trimers that point perpendicularly away from the viral membrane. Retroviruses, paramyxoviruses, filoviruses, and orthomyxoviruses all contain class I fusion proteins. Upon activation, the fusion peptide, located at or close to the N-terminal end of each protein, is released. This process is accompanied by a large conformational change into an extended coiled-coil that contains three α-helices. The following refolding toward a (low-energy) hairpin-like post-fusion conformation of the coiled-coils is thought to lead to the approach and eventually to the merger of the viral and cellular lipid membranes.

Class II fusion proteins–contained in togaviruses, hepadnaviruses, and flaviviruses (Stiasny and Heinz, 2006)–are mostly composed of beta-strands, and the fusion peptide is located in an internal loop rather than at the N terminus. Among the best-characterized examples are the fusion glycoprotein E of the tick-borne encephalitis (TBE) virus and the protein E1 of the Semliki Forest virus (SFV). In the former case, the proteins form heterodimers (together with a viral accessor protein) and in the latter case, homodimers. These prefusion dimers have their long axis oriented roughly parallel to the viral membrane where they contribute to the formation of an ordered icosahedral shell that increases the structural stability of the virus envelope. Fusion is activated by low pH, which induces a major oligomeric rearrangement (with only minor conformational changes) leading to a homotrimeric state for both E and E1. This step is accompanied by the insertion of the fusion peptide into the target membrane and a subsequent folding-back process which leads to the final merger of the two membranes.

Not all known viral fusion proteins belong to either class I or class II (Kielian and Rey, 2006). Fusion proteins of rhabdoviruses and herpesviruses display properties that possibly constitute another class. Structurally, they contain a mixture of α-helical (in particular three-stranded-coiled coils) and beta-sheet secondary structural elements. Their conformational changes induced by low pH in the absence of a target membrane are (in contrast to class I and II) reversible.

12.3.3
Hemagglutinin

The fusion glycoprotein from influenza virus (member of the family of orthomyxoviruses) is HA. Being extensively studied (Bentz and Mittal, 2003), it forms the canonical member of class I fusion proteins. HA is rendered fusion competent after cleavage by cellular proteases into the two subunits HA1 and HA2. HA1 is a globular subunit that contains the sialic acid binding domain and HA2 includes the hydrophobic fusion peptide and the transmembrane domain. In the prefusion state, three HAs form a mushroom-like trimer with the HA1 subunits topping a triple-stranded coiled-coil formed by the HA2 subunits. The fusion peptide is buried within the HA2 trimer. After endocytosis the virus is exposed to a mildly acidic pH in the endosome. This induces a major conformational change. HA1 separates and through a loop-to-helix transition HA2 expels into an extended conformation, terminated by the fusion peptide which inserts into the target membrane (Figure 12.5 for the boomerang-like membrane structure of the fusion peptide). Host and target membrane are now connected through the fully extended HA2 subunits of the fusion proteins. To initiate membrane deformations, a number of HA trimers are thought to arrange into a rosette-like cluster. Then, a folding back of the HA2 subunits through a helix-to-loop transition would plausibly generate a merger of initially the outer monolayers of host and target membrane (possibly through a stalk) which further evolves into a fusion pore. The sequence of these events is illustrated in Figure 12.6 (Acheson, 2007).

12.4
Cellular Fusion

Various biological processes involve cellular fusion, among them vesicular trafficking (intracellular fusion), as well as sexual reproduction and formation of multinucleated cells (cell–cell fusion). Fusion of biological membranes is tightly regulated by a fusion machinery that involves a multitude of proteins. How they act together is the subject of intensive research, especially for the specific case of synaptic vesicle fusion. Principal questions concern the diversity of the fusion pathway: Is there a universal fusion scheme with common intermediates? If so, do the intermediates resemble those of the fusion between bare membranes? And finally, how actively is the lipid membrane involved?

Two principal views on the nature of the fusion process are expressed in *protein-* and *lipid-based* models of fusion pores (Mayer, 2001). The former consists of transmembrane proteins that line up a fusion pore. This is envisioned to be similar to a gap junction where two hemichannels (connexons) combine across the two membranes into a pore (Lindau and Almers, 1995). Protein-based fusion pores are invoked, for example, to explain ion channel-like dynamics of pore opening and closing. In the other (lipid-based) model, the fusion proteins mainly reduce the large energy barriers that exist for fusion of bare membranes. This is accomplished by closely apposing the membranes, affecting their elastic properties, and locally perturbing the bilayer structure. Here, the energy landscape is structurally conserved compared to bare membranes and thus similar non-bilayer intermediates (such as stalks and hemifusion diaphragms) exist (Chernomordik and Kozlov, 2003).

12.4.1
SNAREs

Intracellular compartments such as the ER, lysosome, and Golgi apparatus participate in vesicular trafficking

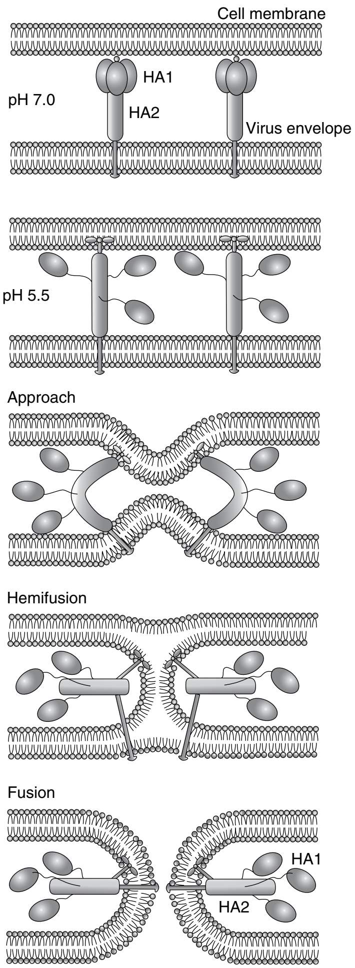

Fig. 12.6 Schematic illustration of fusion between influenza virus and endosomal membrane mediated by hemagglutinin, with permission from Acheson (2007).

and thus engage in membrane fusion events. Fusion also occurs in exocytosis, which is the final step in the secretory pathway and refers to the fusion of trafficking vesicles with the plasma membrane. We distinguish between constitutive (not triggered by Ca^{2+}) and Ca^{2+}-regulated exocytosis (Jackson and Chapman, 2006). The latter includes fusion of neurotransmitter-filled presynaptic vesicles with the plasma membrane where "full-collapse" and "kiss-and-run" fusion constitute two different modes of a vesicle recycling process (Harata, Aravanis and Tsien, 2006). Both secretory pathways involve a similar fusion machinery centered about SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor) complexes, which are widely considered to be crucial for the fusion between transport vesicle and plasma membrane. Specific sets of SNAREs exist for each fusion pathway and specificity is ensured by the recruitment of cognate SNAREs to the corresponding fusion sites (Bethani *et al.*, 2007).

Synaptic SNARE complexes contain a highly conserved core that consists of a parallel four-helix bundle originating from three different SNAREs: syntaxin (which is associated with the plasma membrane), two helices from SNAP-25 (synaptosome-associated protein of 25 kDa), and synaptobrevin (also referred to as *vesicle-associated membrane protein* or *VAMP*). The coiled-coil four-helix bundle contains conserved heptad repeats and is highly stable. A model of a SNARE complex (and synaptotagmin) is shown in Figure 12.7. Interestingly, each helix contributes a highly conserved ionic amino acid side chain to the hydrophobic center of the helix bundle; one arginine (R) and three glutamine (Q). The structural conservation of a 1 : 3 ratio between R and Q has lead to the new nomenclature of Q-SNAREs and R-SNAREs, replacing the original t-SNAREs (t-target) and v-SNAREs (v-vesicular).

The emphasis on SNARE complexes as a "minimal fusion machinery" originates to some extent from their ability to induce fusion *in vitro* when the corresponding SNAREs are reconstituted into separate liposomes (Weber *et al.*, 1998). Yet, fusion under these conditions is infrequent and slow–on a timescale of minutes as compared to milliseconds for synaptic fusion. A suggested mechanism for the docking of vesicles involves the "zippering" of SNARE complexes. Beginning at the membrane-distal N-terminal ends and proceeding toward the membrane-proximal C-termini, the membranes are pulled together and thus brought to close apposition. It is likely that the energy released during the formation of these so-called SNAREpins is used to produce fusion intermediates. Interestingly, the propensity to fuse is completely abolished if the two transmembrane domains of the SNARE complex (from syntaxin and synaptobrevin) are replaced by lipid anchors (McNew *et al.*, 2000). Vesicles are still being docked onto each other but fusion appears to require more than merely close contact. Transmembrane segments of fusion proteins appear to generally participate in the fusion reaction, perhaps by perturbing

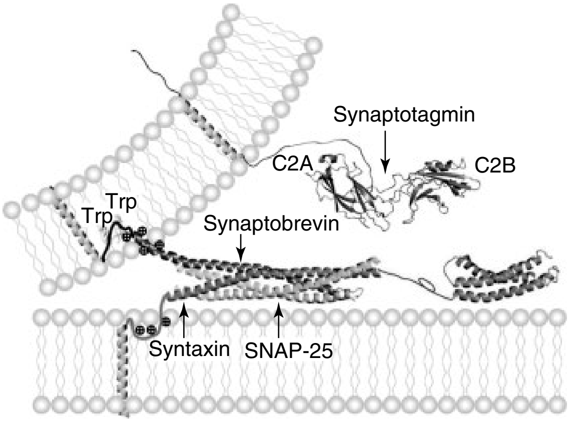

Fig. 12.7 A Model of a SNARE complex and synaptotagmin; with permission from Jackson and Chapman, 2006.

the bilayer, inducing membrane tension or fencing off the hemifusion structure (Langosch, Hofmann and Ungermann, 2007).

Most studies of reconstituted synaptic SNARE-mediated fusion systems confirm the need to add a calcium sensor in order to accelerate fusion (Stein *et al.*, 2007). Present evidence points at an ability of the calcium sensor synaptotagmin to promote curvature in the target membrane (Martens, Kozlov and McMahon, 2007). Indeed, synaptotagmin interacts in the presence of Ca^{2+} with anionic phospholipids through its cytoplasmic C2 tandem domain (C2A and C2B; Figure 12.7) thereby inserting four hydrophobic loops partially into the lipid bilayer. Such insertions generally affect the spontaneous curvature and thus possibly reduce the energy barrier of the fusion reaction (Zimmerberg and Kozlov, 2006). Despite recent progress, to date no fusion system has been reconstituted that fully reproduces the dynamics of synaptic vesicle fusion. How exactly SNAREs and interacting proteins fuse membranes remains to be established.

12.4.2
Cell–Cell Fusion

Cell–cell fusion (Chen *et al.*, 2007) begins with sperm–egg fusion during mammalian fertilization and continues during development. Here, it occurs during skeletal muscle differentiation when many mononucleate myoblasts fuse into multinucleate muscle fibers. Multinucleated cells can also form upon fusion of macrophages into osteoclasts–bone-resorbing cells–and giant cells. Finally, cell–cell fusion contributes to the differentiation of the placenta where multinucleated cells (syncytiotrophoblasts) form a thick layer that serves as barrier between maternal and fetal blood vessels. Cells fuse not only during development but also as a result of disease. This is evidenced by the fusion of somatic cells induced through viruses. Generally, the molecular events that underlie cell–cell fusion remain largely unknown.

A prototype for studying developmental fusion is the nematode Caenorhabditis *elegans*. Syncytial cells in this roundworm form at all developmental stages. Most are binucleate but the epidermal giant cells grow to a total of 138 nuclei. So far, two single-pass transmembrane fusion proteins have been identified, *epithelial fusion failure 1* (EFF-1) and *anchor-cell fusion failure 1* (AFF-1), which independently regulate the fusion of different cell types (Oren-Suissa and Podbilewicz, 2007). The gene encoding for EFF-1 also encodes for a hydrophobic peptide that seems to localize EFF-1 to sites of cell–cell contact prior to fusion (del Campo *et al.*, 2005). The two fusion proteins constitute the founding members of the family of developmental fusogens. The proteins contain large ectodomains with 16 conserved cysteins which perhaps suggest the presence of a ‘‘zippering’’ mechanism, although different from that leading to SNARE complexes. As opposed to the cognate pairing of SNAREs, EFF-1 and AFF-1 require a homotypic arrangement (i.e. the same protein needs to be present on both membranes). Even though the molecular mechanism of EFF-1 and AFF-1-mediated fusion is unknown, it likely involves a hemifusion intermediate.

Sperm–egg fusion in mammals is preceded by a number of prefusion priming events. One is the fusion of the acrosome’s outer membrane with the sperm’s plasma membrane. This allows the enzyme-rich content of the acrosome–a cap-like organelle between the sperm's plasma membrane and nucleus–to secrete. This Ca^{2+}-regulated exocytosis involves a variant of the SNARE-based fusion machinery (Mayorga, Tomes and Belmonte, 2007). Only after subsequent penetration of the sperm into the zona pellucida–a glycoprotein membrane surrounding the plasma membrane of an oocyte–can fusion occur between the plasma membranes of sperm and egg. To date, some of the players of sperm–egg fusion have been identified; others previously hypothesized were shown to be dispensable (Rubinstein *et al.*, 2006).

Myoblast fusion leads to skeletal muscle fibers; cells in these fibers have hundreds of nuclei. Fusion proceeds from "founder cells" that fuse with fusion-competent cells. A number of proteins have been identified that are involved in myoblast fusion. Yet, none of them contains familiar fusion motifs such as fusion peptides or coiled-coil helix bundles, suggesting that (as for EFF-1 and AFF-1) the fusion mechanism is different.

Placental fusion (i.e. the fusion of placenta trophoblasts into syncytiotrophoblasts) is interesting from an evolutionary perspective: for higher primates and some rodents, it requires the protein syncytin which is related to the envelope proteins of endogenous retroviruses (ERVs). This suggests that a captured (class I) fusion protein catalyzes this fusion reaction. In fact, there is evidence that the retroviral genes were integrated and adapted for placenta trophoblasts fusion twice and independently in higher primates and rodents (Oren-Suissa and Podbilewicz, 2007).

12.4.3
Fusion in Mitochondria

Mitochondria are double-membrane intracellular organelles that besides providing the cell with adenosine triphosphate fulfill a large number of additional functions. Originating from a bacterial ancestor, they have evolved into semiautonomous entities with variable shape and morphology. Even more, mitochondria constantly redefine their identity by undergoing fusion and fission. Suppression of fusion leads to defragmentation, suppression of fission to elongation. The balance of these two antagonistic processes provides a dynamic equilibrium that appears to be important in a yet not well-understood manner. Fusion and fission allow mitochondria to communicate with each other, and both are needed to maintain proper respiratory function. A possible advantage of the continuous remodeling is greater efficiency of inheritance and intracellular distribution of mitochondrial DNA (Hoppins, Lackner and Nunnari, 2007). In addition, mitochondrial fusion and fission appear to correlate with the protection from and promotion of apaptosis.

There are distinct machineries for fusion and fission in mitochondria. Fusion of the mitochondia's outer membranes in mammalian cells depends on the GTPases mitofusins, Mfn1 and Mfn2. (Similar proteins exist in other organisms.) They are thought to mediate the tethering of the outer membranes based on a homotypic arrangement (i.e. their presence on both outer membranes) and interaction through a coiled-coil of their heptad repeat regions (Chan, 2006). The subsequent events that induce fusion have not yet been identified. Note that fusion of outer and inner membranes is correlated, but the inner membranes have a separate fusion machinery.

12.5
Modeling Fusion

Experimental data inspire models that feed back into the design of experiments. Of course, this general scheme applies to the fusion of lipid membranes as well. Modeling is therefore not only a supplement but also an integral part in our process of understanding membrane fusion. This chapter treats *modeling* and *simulating* fusion as separate sections because computer simulations are sometimes considered as experiments *in silico*. Yet, the separation between the two is not well defined because computer simulations often employ a set of assumptions comparable to phenomenological models and, conversely, phenomenological models can often only be evaluated using powerful computers.

Lipid membranes are self-assembled materials that interact with each other and resist mechanical forces to some degree. If subject to stress, membranes may respond in numerous ways, depending on the energy landscape and the ability to explore this landscape through fluctuations. Phenomenological models of membrane fusion drastically reduce the dimensionality of this energy landscape by considering only a small number of degrees of freedom, the so-called order parameters. This kind of modeling can be very valuable because it potentially identifies the most relevant degrees of freedom and underlying mechanisms. For example, fusion intermediates were first suggested and analyzed based on phenomenological modeling. Some of these models are certainly too simple but their conceptual value is highly significant.

12.5.1
Forces between Membranes

Before membrane fusion can be initiated, the two membranes must approach each other. Only uncharged (or very weakly charged) membranes have a small equilibrium distance of a few (2–3) nanometers (Rand and Parsegian, 1989). Charged membranes–including biological membranes–usually repel each other even at larger distances. A short account of the different forces that act between two membranes includes the following.

12.5.1.1 Electrostatic Forces

Upon approach of two charged membranes in aqueous solution, their respective diffuse layers of counter- and co-ions are perturbed. A force arises that is usually repulsive if both membranes are anionic (for cationic membranes, see Section 12.2.6). A useful model to describe this force is provided by Poisson–Boltzmann theory which assumes point-like ions and neglects all correlations (Andelman, 1995). Poisson–Boltzmann theory always predicts repulsion between two negatively charged membranes. However, if one of its assumptions is not fulfilled, Poisson–Boltzmann theory fails and attractive interactions can occur. This is the case if the membranes are highly charged or if the ions in solution are either multivalent or have an internal structure. Predicting the force is then not a simple matter.

12.5.1.2 Van der Waals Forces

Induced dipole–dipole interactions lead to an (usually) attractive potential $\sim r^{-6}$

which can be integrated over two membranes. This gives rise to an attractive force per unit area $-H/(6\pi r^3)$ for membrane-to-membrane distances r much smaller than the membrane thickness d and $-2Hd^2/(\pi r^5)$ for $r \gg d$. Here, $H \approx k_BT$ is the Hamaker constant. In colloid science, van der Waals and electrostatic forces together constitute DLVO (Derjaguin–Landau–Verwey–Overbeek) theory.

12.5.1.3 Undulation Forces

Bending fluctuations of two fluid membranes (characterized by the bending stiffness κ; see Eq. (1)) are suppressed when they approach each other, leading to a repulsive force per unit area of magnitude $3\pi^2(k_BT)^2/(64\kappa r^3)$ as a function of the membrane-to-membrane distance r.

12.5.1.4 Hydration Forces

Structural ordering of water molecules occurs in lipid membranes close to the apolar/polar interface. For two identical membranes, interference of the ordered layers leads to a short-range repulsive force per unit area of magnitude $C\exp(r/\lambda)$ with $C = 10^6–10^8\text{N m}^{-2}$ and $\lambda = (0.15–0.3)$ nm. This force dominates at membrane-to-membrane distances r smaller than about 1–3 nm. Note that the hydration force can also be attractive for surfaces that induce different directionality of the water ordering (Rand *et al.*, 1988).

12.5.1.5 Polymer-Induced Forces

The presence of water-soluble polymers can modify the interaction forces between two membranes in several ways (Netz and Andelman, 2003). Membrane-anchored polymers will contribute to the steric repulsion force between two membranes due to their conformational entropy loss. If free polymers are present in the aqueous solution, there will be an attractive depletion force. Finally, membrane-adsorbing polymers may give rise to a bridging interaction that can be attractive or favor an equilibrium distance.

The repulsion between bare (protein-free) membranes can be overcome by using divalent cations (Section 12.2.2), polymers such as PEG (Section 12.2.3), or oppositely charged membranes (Section 12.2.6). Initiating contact between biological membranes is accomplished by proteins. These proteins tether membranes together; as, for example, SNAREs accomplish through formation of four-helix bundles (Section 12.4.1), viral fusion proteins achieve via receptor-specific binding (Section 12.3.2), or mitofusins are thought to do for mitochondrial membranes (Section 12.4.3).

12.5.2
Membrane Elasticity

Most phenomenological modeling efforts of fusion intermediates are based on the elastic behavior of lipid layers. A number of deformation modes are commonly discussed; they include stretching, curvature, and tilt; as illustrated in Figure 12.8. In a lateral stretching deformation the average cross-sectional area a per lipid deviates from its equilibrium value $a_0 \approx 0.6\ \text{nm}^2$. The corresponding free energy, measured per unit area of the lipid layer, can be written as $(K/2)(a/a_0 - 1)^2$ where $K \approx 20\ k_BT/\text{nm}^2$ is the lateral compressibility modulus. A second mode corresponds to a bending deformation which can be described in terms of the two principal curvatures c_1

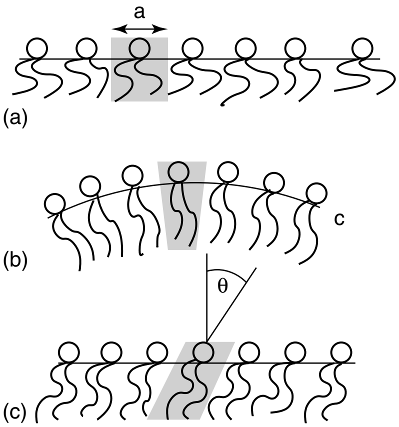

Fig. 12.8 Schematic illustration of three elastic deformation modes of a fluid lipid layer: (a) stretching, (b) bending, and (c) tilt. Here, *a* is the lateral cross-sectional area per lipid, *c* is the curvature of the lipid layer, and θ is the tilt angle of the lipid director.

and c_2 at any given location within the lipid layer. The corresponding bending energy F, measured per unit area A, can be written as (Helfrich, 1973)

$$\frac{F}{A} = \frac{\kappa}{2}\left(c_1 + c_2 - c_0\right)^2 + \bar{\kappa} c_1 c_2 \qquad (1)$$

Here, $\kappa \approx 10\, k_B T$ and $\bar{\kappa}$ are the bending stiffness and Gaussian modulus, respectively. The bending stiffness relates to changes in the mean curvature $(c_1 + c_2)/2$ or, equivalently, to a *splay* deformation at the level of individual lipids. The Gaussian modulus $\bar{\kappa}$ accounts for the resistance with respect to changing the Gaussian curvature $c_1 c_2$ or, at the level of individual lipids, for a *saddle–splay* deformation. Consequently, κ and $\bar{\kappa}$ can alternatively be referred to as *splay modulus* and *saddle-splay modulus*. The intrinsic tendency of a lipid layer to adopt a preferred curvature is expressed by the spontaneous curvature c_0 in Eq. (1). Note that F in Eq. (1) is invariant with respect to $c_1 \rightarrow c_2$ and $c_2 \rightarrow c_1$ which accounts for lateral fluidity. Moreover, the curvatures c_1 and c_2 must be measured at the so-called neutral surface where stretching and curvature deformations of the lipid layer decouple.

Another elastic mode is associated with a tilt deformation. Here, the average direction of the lipid molecules deviates from the normal direction of the lipid layer. Denoting the angle between the two by θ, the free energy of a tilt deformation, measured per unit area, can be written as $(\kappa_t/2)\theta^2$ where $\kappa_t \approx 20\, k_B T/\text{nm}^2$ is the tilt modulus (May *et al.*, 2004).

The different deformation modes can be expressed together in terms of a vector field $h\mathbf{n}$ where h is the local effective length of the lipids and $\mathbf{n}$ is a field of unit vectors, describing the directions into which the lipid tails point on average. Note that $\mathbf{n}$ is referred to as a *director* field in analogy to the theory of liquid crystals. The following part of the free energy per unit area

$$\frac{\kappa}{2}(\nabla \cdot \mathbf{n} - c_0)^2 + \frac{\kappa_t}{2}(\mathbf{n} - \nabla h)^2 \qquad (2)$$

(where ∇ denotes the nabla operator) then shows that splay can be produced from both curvature $\nabla^2 h$ at constant tilt and changing tilt at constant curvature (Hamm and Kozlov, 2000; Fournier, 1998). General free energy expressions that are based on Eq. (2) can be used to analyze elastic membrane deformations, including fusion intermediates.

12.5.3
Membrane Pores

The formation of pores often appears as alternative outcome in membrane fusion assays, signified by content leakage of vesicles. Pore formation in a bare membrane can be induced by lateral tension and, similar to fusion, requires an activation energy. This is seen most simply in a model inspired by classical nucleation theory (Litster, 1975). Here, a circular pore of radius r and line tension of the pore rim λ in a membrane that is subject to lateral tension Λ has the free energy

$$\lambda 2\pi r - \Lambda \pi r^2 \tag{3}$$

which adopts a minimum at $r = 0$ and a maximum at $r = \lambda/\Lambda$. Unbounded pore expansion thus occurs for an activation energy larger than $\pi\lambda^2/\Lambda$. The lateral tension Λ can generally have electrical or mechanical origin. The former is the basis for electroporation (Chang *et al.*, 1992), whereas the latter is thought to play an important role in the rupture of the hemifusion diaphragm (Figure 12.2d and e). The line tension λ–the energy needed to create a membrane rim of unit length–depends on the molecular structure of the involved lipids and is typically found to be in the range of $\lambda = (2.5–7.5)\ k_B T/\text{nm}$. The exposure of hydrocarbon chains to the aqueous environment would predict a much larger value, $\lambda = \gamma d = 36\ k_B T/\text{nm}$, based on a hydrocarbon water surface tension $\gamma = 12\ k_B T/\text{nm}$ and a hydrophobic membrane thickness of $d = 3\text{nm}$. The much lower value of λ found experimentally indicates a structural rearrangement of the rim-forming lipids. That is, some lipids reorient themselves in order to use their polar headgroups to protect the hydrocarbon chains from exposure to water as illustrated in Figure 12.9. The assumptions of cylindrical pores and constant line tension λ (Eq. (3)) need not be fulfilled in real systems. Small line tension will lead to significant fluctuations in pore shape or even in the spontaneous formation of transient pores. Also, the line tension λ is generally not a constant, especially not for small pore sizes where rim–rim interactions become relevant.

12.5.4
Modeling Fusion Intermediates

A stalk is a lipid connection between the two proximal monolayers of two lipid membranes, illustrated in Figure 12.2b. Its existence during the transition from the lamellar-to-inverted nonlamellar phases has been shown experimentally (discussed in Section 12.2.1), and some indirect evidence suggests its presence in the fusion of bare and biological membranes as well.

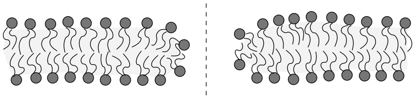

Fig. 12.9 Schematic illustration of a cross-section through a membrane pore. The broken line indicates the axis of cylindrical symmetry.

Since its postulation (Kozlov and Markin, 1983), the stalk model has been revised several times. The different generations of stalk models have been discussed recently (Siegel, 2004). The original stalk model was based entirely on the bending energy of the individual monolayers in each of the two fusing membranes; see Eq. (1). It made a number of predictions that agree with experimental observations, including the dependence of hemifusion rates on membrane composition. Specifically, the addition of lipids with $c_0 < 0$ to the proximal monolayers of two apposed membranes is predicted to render stalk formation more favorable. This is indeed observed experimentally as discussed in Section 12.2.4.

A different possibility to increase fusion rates is by adding alkanes (Walter, Yeagle and Siegel, 1994). The mechanism is likely to be the same as for the well-known stabilization of the inverse hexagonal phase by alkanes. In both cases, the packing energy of the hydrocarbon tails is reduced by allowing alkanes to partition into the interstitial region–the contact region of three monolayers. The original stalk model was not able to account for this observation which motivated Siegel to add to the bending energy a chain packing contribution (Siegel, 1993; Siegel, 1999). A problem that emerged in calculating the optimal energy of the modified stalk model was its high energy, generally exceeding 100 k_BT.

The problem of the large stalk energy was solved by allowing for edges in the shape of the stalk (Kozlovsky and Kozlov, 2002). The existence of edges is intimately related to nonvanishing tilt of the lipid chains. Tilt was introduced in Section 12.5.2 as an elastic deformation mode of a lipid layer. Appropriate tilt deformations completely eliminate the interstitial energy. As a result, the total stalk energy is contained in its elastic deformation energy. Yet, even when accounting for tilt, the energy remains large for a smooth stalk. What reduces the stalk energy to values below 40 k_BT is the existence of edges both in the waist of the stalk and at the dimples of the distal monolayers. An example of a calculation that compares a stalk with and without edges is shown in Figure 12.10.

According to the stalk-pore model, an initial stalk can radially expand into a hemifusion diaphragm; see Figure 12.2. This process is predicted to occur spontaneously if the lipid layer has a sufficiently large negative spontaneous curvature. In this case, the rim of the hemifusion diaphragm creates a lateral tension in the enclosed bilayer that may be sufficiently large to lead to membrane rupture and thus formation of a fusion pore (Kozlovsky, Chernomordik and Kozlov, 2002). Yet, this is not the only possible scenario. Different pathways have been suggested based not only on computer simulations (discussed in Section 12.6.3) but also on membrane elasticity. For example, the formation of multiple stalks (somewhat similar to Figure 12.3b) could lead to pore formation through stalk coalescence (Lukatsky and Frenkel, 2004).

12.6
Simulating Fusion

Computer simulations generally constitute a rapidly growing, diverse set of methods, ranging from atomistic to solvent-free approaches. Among those,

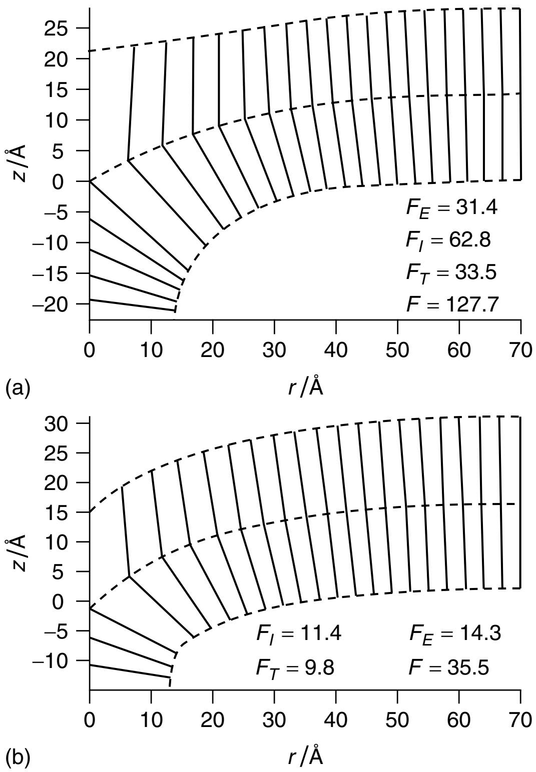

Fig. 12.10 Stalk structures on the basis of membrane elasticity theory, with permission from May (2002). Both stalks were calculated for the same system but the upper one was constrained to be smooth everywhere. The broken lines mark the polar–apolar interfaces and the bilayer midplane. The solid lines denote local lipid directors. For each structure, the energies of the distal monolayers (F_E), proximal monolayers (F_I), and the remaining lipid tether (F_T) are indicated. The total stalk energy is $F = F_E + F_I + F_T$.

atomistic MD simulations represent a method based on *first principles*. This most closely corresponds to actually producing the events of an experiment in silico. Accessible time and length scales are still restricted; atomistic simulations of fusion events are just starting to become feasible. Coarse-grained simulations allow to simulate larger systems. The term *coarse-graining* generally refers to ignoring certain degrees of freedom. This can range from joining groups of atoms (as in most coarse-grained MD simulations) to neglecting the entire solvent (as in solvent-free simulations). Which degrees of freedom can be ignored is often nontrivial, especially for biological systems that have an intrinsic multiscale character. This includes biological membrane fusion where, on the one hand, hundreds of lipids are involved and, on the other hand, a single point mutation of the fusion proteins may completely abolish fusion competence. Multiscale simulation methods may eventually provide means to self-adjust the coarse-grainedness of a simulation in space and time.

12.6.1
Molecular Dynamics Simulations

Atomistic MD simulations provide the most detailed information of structure and motion of lipid membranes. All atoms in a given system are accounted for explicitly as classical particles, and all interactions–bonded and nonbonded–are represented by suitable and sufficiently simple potentials. At each time, the forces acting on all atoms can be computed which allows to numerically solve Newton's equations of motion. The small time step needed for this integration ($\approx$ 2 fs) limits the total simulated time of a system with typical linear extension of 20 nm to the order of 10 ns. This is much less than the sub-millisecond timescale of the fastest known biological fusion (synaptic vesicle fusion). Therefore, almost all attempts to model membrane fusion on the basis of MD employ coarse-grained models. Still, the feasibility of atomistic MD simulations to produce fusion on the nanosecond timescale from a pre-formed stalk was recently demonstrated (Knecht and Marrink, 2007).

In coarse-grained MD simulations a group of atoms are represented by a single interaction site. Coarse-grained lipids contain only a few different segment types (such as polar, nonpolar, apolar, and charged (Marrink *et al.*, 2007)) which greatly reduces the number of required interaction parameters. The design of coarse-grained simulations is guided by matching their predictions with data from atomistic simulations and experiments. Depending on the model, coarse-grained MD simulations sample systems with larger spatial ($\approx$50 nm) and temporal extension (μs). This renders entire fusion paths accessible. By and large, available simulation results are consistent with the stalk-pore hypothesis. That is, a stalk initially connects the proximal leafs of two apposed membranes and then transforms into a transmembrane contact. Upon further radial expansion, a metastable hemifusion diaphragm appears that subsequently ruptures and thus gives rise to a fusion pore. Also in agreement with predictions from continuum stalk models, lipids rearrange through tilt and splay to prevent formation of a large void space in the interstitial regions of the stalk, and nonlammellar lipids strongly affect fusion activation energies (Marrink and Mark, 2003; Stevens, Hoh and Woolf, 2003; Smeijers *et al.*, 2006; Kasson and Pande, 2007). Figure 12.11 displays an example of a specific coarse-grained MD simulation where a small vesicle fuses with a planar bilayer (Smeijers *et al.*, 2006). Shown is a sequence of events characteristic for the stalk-pore model. An interesting aspect of this particular simulation is the transient formation of a hydrophobic void (Figure 12.11b).

Extensive sampling of many MD trajectories for the fusion of small vesicles suggests the existence of two distinct pathways: opening of the fusion pore directly from the "transmembrane contact"-intermediate or only after the formation of an extended hemifusion diaphragm (Kasson *et al.*, 2007).

12.6.2
Dissipative Particle Dynamics

Dissipative particle dynamics (DPD) is a particle-based simulation method that preserves correct hydrodynamic behavior at mesoscopic length and time scales. Conservative, random, and dissipative forces act on beads which represent fluid droplets–clusters of molecules–with all internal degrees of freedom integrated out. The conservative forces can be used to construct connectivities that represent complex molecules or molecular aggregates, such as polymers or lipids. Soft interaction potentials allow for large timesteps in integrating Newton's equations of motion which adopt

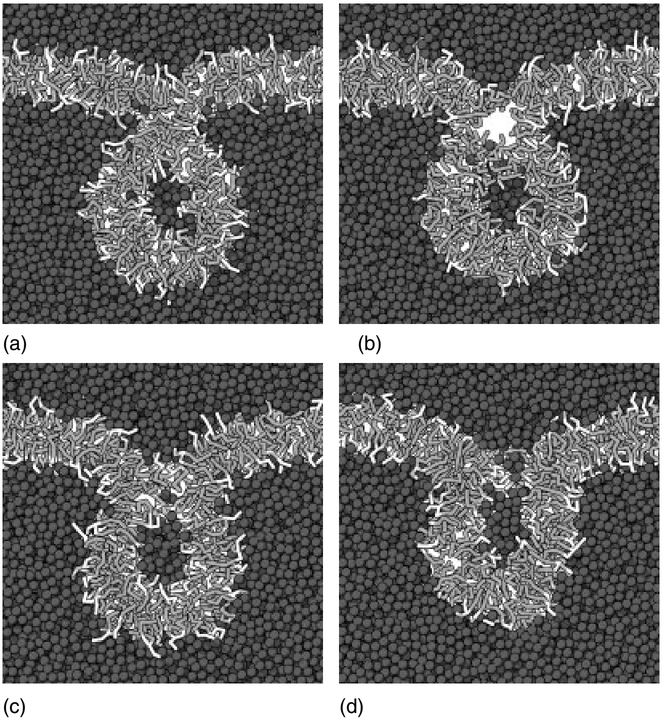

Fig. 12.11 Example of a coarse-grained MD simulation result from Smeijers *et al.* (2006), with permission. Shown is the fusion of a small vesicle with a planar bilayer. The snapshots refer to (a) stalk at 15.4 ns, (b) radial expansion of stalk and formation of a hydrophobic void 15.6 ns, (c) a hemifusion diaphragm at 15.7 ns, (d) fusion pore at 16.5 ns.

the form of stochastic differential equations. Application of the method allows to simulate lipid vesicles that are considerably larger in diameter ($\approx$30 nm) compared to those in coarse-grained MD simulations ($\approx$15 nm). Recent studies have focused on how lateral tension in a planar lipid membrane promotes the fusion with a vesicle in close proximity (Shillcock and Lipowsky, 2005). Fusion can be favorable in this case as it relieves the tension without forming an energetically costly pore. Yet, reasonable increase of fusion probability requires large lateral tension, making membrane rupture a frequent event.

12.6.3
Solvent-Free Simulations

The first solvent-free computer simulation of vesicle fusion employed Brownian dynamics. This method too is based on a stochastic differential equation–the Langevin equation–but does not reproduce hydrodynamic behavior. Fusion of two vesicles with a total of 1000 rod-shaped lipids predicts a fusion pathway quite distinct from the stalk-pore model. Here, a stalk forms and expands asymmetrically into a bent structure which leads to pore opening (Noguchi and Takasu, 2001). A related scenario is predicted on the basis of Monte Carlo simulations using a lattice description for single chain amphiphiles that are not far from the $L_\alpha \rightarrow H_{II}$ transition. Two closely apposed planar bilayers under tension initially develop a stalk that induces multiple pore formation close to the stalk in both bilayers. The synchronous appearance of two pores in direct apposition induces a zipper-like propagation of the stalk along the hole's edges, resulting in a fusion pore (Müller, Katsov and Schick, 2002). These two asymmetric stalk propagation models receive some support from coarse-grained MD simulations (Smeijers *et al.*, 2006).

12.7
Conclusions

Studying membrane fusion is an interdisciplinary process in which physics, chemistry, and biology meet each other. None of these fields alone provides sufficient tools to fully understand how fluid-like, highly dynamic bilayers are brought together and then merge by a specialized protein machinery. One of the difficulties in probing the fusion process is its spatial and temporal confinement: only a small fraction of all available lipids and proteins carry out the fusion act. This requires special techniques to selectively probe these molecules. Another challenge is the intrinsic disorder of lipid membranes which renders entropy a major contribution to the free energy. Indeed, measurements often suggest an ensemble of possible outcomes and computer simulations are just beginning to capture this variability.

Despite the large body of experimental data, there is as yet no rigorous molecular understanding of membrane fusion, neither for bare nor biological membranes. Experiments support a number of models for membrane fusion; most of these are discussed in this chapter. One of them, the stalk-pore model, is currently considered the most universal fusion pathway with relevance to certain fusion types of bare as well as biological membranes. The latter includes viral and SNARE-based fusion. Here, fusion appears to follow a lipid-based pathway with similar intermediates as for bare membranes. Little is known on a molecular level about other fusion types, and it remains to be seen if these follow a similar general fusion path.

Acknowledgments

I would like to thank Drs Gene Berry and Dave Siegel for their helpful comments. The author acknowledges support during the preparation of this chapter from NIH through R15-GM077184 and NSF through DMR-0605883.

Glossary

Coiled-coil: structural motif in proteins where two or more α-helical subunits are wrapped around each other forming a long extended rod-like segment.

Ectodomain: the part of a membrane protein that extends into the extracellular space.

Endoplasmatic fusion: fusion events that occur within a cell. Examples include fusion events during vesicular membrane transport between organelles, in mitochondria, in the Golgi apparatus, and in other inner organelles.

Exocytosis: fusion of the plasma membrane with secretory vesicles, which constitutes the final step in the secretory pathway.

Exoplasmatic fusion: fusion that involves the merger of plasma membranes.

Hemagglutinin: a glycoprotein from influenza (and other) viruses, which mediates binding and fusion with a target cell; see Section 12.3.3

Hydration force: a structural force between two surfaces immersed in aqueous solution due to the ordering of water molecules.

Lipids: large class of hydrophobic, fat-soluble molecules including waxes, oils, phospholipids, and steroids. Membrane-forming lipids are amphiphilic; they combine hydrophilic and hydrophobic properties.

Lipid polymorphism: amphiphilic molecules such as lipids are able to self-assemble into various aggregation geometries

Stalk: lipidic connection between the proximal leafs of two closely apposed lipid bilayers; see Section 12.2.1.

Syncytia: multinuclear cells that form through cell–cell fusion.

SNARE: soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor. A protein family involved in the fusion of intracellular transport vesicles.

Spontaneous curvature c_0**:** denotes the propensity of a lipid layer to adopt curved geometries; see Eq. (1)

Undulation force: repulsive force between two apposed membranes, caused by steric repulsion due to bending fluctuations.

Vesicle: aqueous compartment enclosed by one (unilamellar) or several (multilamellar) lipid bilayers.

13.1
Introduction

The vibrational Raman effect, which was predicted on the basis of theoretical considerations by Smekal (1923) and confirmed experimentally by Raman and Krishnan (1928), was first applied to model peptides in the 1950s by Edsall and collaborators (Edsall, Otvos and Rich, 1950; Garfinkel, 1958a, 1958b, 1958c, 1958). Raman spectroscopy was subsequently demonstrated as an effective experimental probe of nucleic acids and native proteins by R. C. Lord and collaborators in the late 1960s and early 1970s (Lord and Thomas, 1967b, 1968; Lord and Yu, 1970a, 1970b). With the advent of the continuous wave laser as an effective excitation source for biomolecular applications, the Raman method soon gained use as a structural probe of supramolecular biological assemblies, including viruses (Hartman, Clayton and Thomas, 1973; Miura and Thomas, 1995b; Nemecek *et al.*, 2007; Rodriguez-Casado *et al.*, 2001; Thomas and Murphy, 1975; Thomas *et al.*, 1976; Thomas, Prescott and Olins, 1977; Tsuboi *et al.*, 2003b; Tsuboi, Benevides and Thomas, 2007a; Tuma and Thomas, 1997). Biological applications of Raman spectroscopy are greatly advantaged over infrared spectroscopy by both the relatively low interference of liquid water in the Raman effect and the diversity of sample states amenable to Raman analysis (solutions, suspensions, gels, precipitates, fibers, single crystals, amorphous solids, etc.). These considerations facilitate the correlation of biomolecular solution structures with corresponding high-resolution structures determined by X-ray crystallography (Helfand *et al.*, 2007; Li *et al.*, 1992b; Miura and Thomas, 1994; Thamann *et al.*, 1981; Totir *et al.*, 2007). More recently, the development of improved statistical approaches has allowed exploitation of Raman spectroscopy for detailed quantitative analyses of thermodynamic and kinetic properties of complex biomolecular systems (Hanus *et al.*, 1999, 2001; Nemecek *et al.*, 2008; Prochazka *et al.*, 2002). Concurrent developments in Raman instrumentation, including the advent of charge-coupled-device (CCD) detectors, efficient solid-state lasers, and efficient Raman microscopes, have similarly advanced biochemical, biophysical, pharmaceutical, and commercial applications of the related techniques of polarized Raman spectroscopy, Raman optical activity (ROA), ultraviolet resonance Raman (UVRR) spectroscopy, and

Handbook of Molecular Biophysics. Methods and Applications. Edited by Henrik G. Bohr.

surface enhanced Raman spectroscopy (SERS) (Blanch *et al.*, 2002; Lewis and Edwards, 2001; Mikhonin and Asher, 2005; Mikhonin *et al.*, 2006; Pappas, Smith and Winefordner, 2000; Premasiri *et al.*, 2005; Tsuboi and Thomas, 2007b).

The objective of the present chapter is to consider representative applications of Raman spectroscopy, including UVRR and polarized Raman spectroscopy, that address fundamental questions of virus structure and assembly. The focus is on bacterial viruses (bacteriophages) that comprise only protein and DNA constituents. Often, the structural, mechanistic, and thermodynamic information obtainable from Raman spectra can be augmented by time-resolved data, such as those collected in the course of hydrogen/deuterium (H/D) exchanges of labile protein and DNA sites. UVRR approaches offer advantages of selectivity and sensitivity over conventional Raman spectroscopy, whereas polarized Raman spectroscopy is particularly well suited to determine orientations of specific moieties in viral assemblies.

13.2
Assembly Pathways of Representative Viruses

The maturation pathways of highly organized biomolecular assemblies such as viruses usually proceed in several discrete steps. Figure 13.1 shows this stepwise process for a typical DNA virus, the bacteriophage P22, which infects strains of the bacterium *Salmonella typhimurium* and is considered a paradigm for the assembly of many viruses that package a double-stranded (ds) DNA genome within an icosahedral protein shell (Casjens and Weigele, 2005). As shown in Figure 13.1, the pathway begins with the coassembly of 420 copies of the coat protein subunit (product of viral gene 5, or simply gp5) plus 12 copies of the portal protein subunit (gp1) and approximately 300 copies of the scaffolding protein subunit (gp8) to form a *procapsid*. The procapsid exterior consists of the gp5 shell incorporating the portal channel at a unique vertex, while the gp8 molecules are enclosed within. The procapsid also contains a few copies of the minor (ejection) proteins gp7, gp16, and gp20. At the time of DNA packaging, the procapsid shell matures into an expanded *capsid* shell and expels its scaffolding component. The genome packaging event (DNA translocation), which proceeds through the portal channel, is fueled by the hydrolysis of adenosine triphosphat (ATP) through the action of a virally encoded hetero-oligomeric enzyme called *terminase* (proteins gp2 and gp3). The last step in the assembly/maturation pathway involves the closure of the portal channel by accessory proteins (gp4, gp10, and gp26) and the attachment of six trimeric tailspike proteins (gp9), which serve as the host cell adhesion.

The filamentous bacterial viruses exhibit assembly pathways distinct from those of icosahedral viruses. The best-studied example is that of the filamentous virion Ff (strains fd, f1, and M13) (Figure 13.2), which infects *Escherichia coli*. The viral particle recognizes the conjugative pilus of the host cell and exploits the host transmembrane network of proteins (Tol–Pal system) for penetration. When the viral adhesion protein (pIII) binds to the Tol–Pal complex, the viral capsid is compromised and releases its single-stranded (ss) DNA genome. The major (pVIII) and minor (pIII, pVI, pVII, pIX) proteins of the

Fig. 13.1 The assembly pathway of the *Salmonella* bacteriophage P22, which serves as a model for the assembly of many icosahedral double-stranded DNA viruses (Casjens and Weigele, 2005). The initial step (upper left) is the coassembly of 420 copies of the coat protein (gp5), 12 copies of the portal protein (gp1), approximately 300 copies of the scaffolding protein (gp8), and a few copies of minor ejection proteins (gp7, gp16, and gp20) to form a precursor shell (procapsid) incorporating a unique portal vertex. Subsequently, DNA packaging through the portal is fueled by ATP hydrolysis under the control of the phage terminase (subunits gp2 and gp3) and is accompanied by release of scaffolding and shell maturation. The final steps involve closure of the portal channel by accessory proteins (gp4, gp10, and gp26) and attachment of six trimeric tailspike proteins (gp9). The inset at the lower left shows an electron micrograph of the mature P22 virion.

capsid are disassembled and retained in the host inner membrane for subsequent use in the assembly of progeny virions. The ssDNA genome is converted into a replicative form for expression of viral structural and nonstructural proteins. Ultimately, the progeny virions exit the bacterial cell through a complex transmembrane channel formed from multiple nonstructural viral proteins (Overman and Thomas, 2008). The mature viral particle consists of the ssDNA genome in the form of a covalently closed circle extending from one end of the filament to the other and sheathed by thousands of copies of the major coat protein plus a few copies of each of two minor proteins at each of the filament ends.

Fig. 13.2 The life cycle and assembly pathway of the filamentous bacteriophage Ff, which infects *Escherichia coli* (Overman and Thomas, 2008). Essential features of membrane recognition and penetration are discussed in the text. The mature viral particle consists of a single-stranded DNA genome in the form of a covalently closed circle that extends from one end of the capsid sheath to the other. The sheath comprises thousands of copies of the major coat protein (pVIII) plus a few copies of minor proteins at each filament end. The inset at the lower left shows an electron micrograph of the mature Ff virion.

structures and interactions of molecules by measuring the frequencies (wavenumbers) of molecular vibrations. Although the two methods differ fundamentally in the mechanism of interaction between radiation and matter, one obtains in both cases a vibrational spectrum consisting of a number of discrete bands, the wavenumbers and intensities of which are determined by the nuclear masses in motion, the equilibrium molecular geometry, and the molecular force field. An important advantage of Raman over IR for applications to viral proteins, nucleic acids, and their complexes is the virtual transparency of liquid water (both H_2O and D_2O) in the Raman effect. This greatly simplifies the analysis of solution spectra and also facilitates the investigation of hydrogen-isotope-exchange phenomena. Other notable advantages of Raman spectroscopy are ease of implementation for samples in different physical states (solutions, suspensions, gels, precipitates, fibers, single crystals, amorphous solids, etc.), applicability to large supramolecular assemblies, a spectroscopic time scale ($\sim 10^{-14}$ seconds) that is fast in comparison to both biomolecular structure transformations and protium/deuterium (H/D) exchanges, nondestructiveness of data collection protocols, relatively low mass (<1 mg) and volume ($\sim 1 \mu l$) requirements for most sampling protocols, and freedom from the need for chemical labels or probes. Additionally, a large database of Raman spectra of model compounds has been established for applicability to viral proteins and nucleic acids.

The technique of Raman difference spectroscopy provides a complementary and powerful experimental approach for applications to viruses. For example, digital difference methods can be exploited to: (i) facilitate definitive Raman band assignments by detection of small wavenumber shifts and/or intensity changes accompanying residue-specific isotopic substitutions or mutations (Overman *et al.*, 1994; Overman and Thomas, 1999; Raso *et al.*, 2001), (ii) assess qualitatively and quantitatively the structural changes induced in proteins and nucleic acids when solution conditions, such as temperature, pH, ionic strength, or ligand concentration are altered (Benevides, Overman and Thomas, 2005b; Thomas, 1999; Tuma and Thomas, 2002), (iii) detect localized interactions and conformational changes in viruses (Aubrey, Casjens and Thomas, 1992; Overman *et al.*, 1998a; Wen, Overman and Thomas, 1997; Wen, Armstrong and Thomas, 1999), and (iv) probe changes in solvent accessible surfaces along the viral assembly pathway (Reilly and Thomas, 1994; Tuma, Prevelige and Thomas, 1998b).

Methods of polarized Raman spectroscopy have also been successfully applied to viruses. The data obtained from polarized Raman measurements are particularly informative when the virus specimen can be precisely oriented with respect to the directions of polarization of incident and scattered laser light. This is readily achieved for the examination of oriented filamentous viruses in the Raman microscope (Tsuboi *et al.*, 2003a). A comprehensive review of applications has been given recently (Tsuboi and Thomas, 2007b).

13.4
Experimental Methods for Raman Spectroscopy

Instrumentation for Raman spectroscopy of viruses is generally similar to that employed for investigating other macromolecules in condensed states (solutions, crystals, fibers, etc.) (Pappas, Smith and Winefordner, 2000). Diode-pumped solid-state lasers are available to provide stable excitations throughout the visible and near-infrared (NIR) wavelength regions. Excitation in the 750–800 nm interval, such as those provided at 785 nm by the Invictus laser (Kaiser Optical Systems, Inc., Ann Arbor, MI), offers the additional advantage of freedom from potentially interfering fluorescence transitions. Spectrometers for biomolecular applications ordinarily incorporate the holographic notch filter for rejection of elastically scattered light, a single axial transmissive grating to maximize photon throughput and a liquid-nitrogen-cooled CCD detector to optimize spectrophotometric sensitivity and selectivity. Recent sampling innovations, which are particularly useful for studying time-dependent processes in viruses, include solution flow dialysis (Caille, Pigeon-Gosselin and Pezolet, 1983; Tuma and Thomas, 1996b) and crystal diffusion (Carey, 2006; Helfand *et al.*, 2007). In principle, time-resolved Raman spectroscopy can span a wide temporal domain, from tens of femtoseconds (using pulsed lasers) to indefinitely long periods. The slower structural transformations that characterize viral assembly and maturation processes, including genome packaging enzyme activities, are relatively easily addressed (Jenkins *et al.*, 1999; Li, Johnson and Thomas, 1993b; Tuma and Thomas, 1996b).

Solutions of viruses are generally sealed in thin glass capillaries and thermostated at the appropriate temperature (Thomas and Barylski, 1970) for collection of Raman spectra. The exciting laser beam is focused on the sample volume (1–10 μl) and the light scattered at 90° is directed to the entrance slit of the spectrograph, where it is analyzed and directed to the CCD detector (Tuma *et al.*, 1993).

Solid samples, including oriented fibers and crystals that typically have dimensions of the order ∼100 μm, are most effectively probed by means of a Raman microspectrophotometer, which consists of a confocal microscope coupled to an efficient single grating spectrophotometer. The microscope functions as the sample illumination chamber and typically is coupled to a video camera and monitor to simplify optical alignment and focusing of the laser beam with respect to the sample. The incident laser beam is directed onto the oriented specimen through the microscope objective; the Raman scattering, preferably at 180°, is collected with the same objective and then directed to a beam splitter, polarization analyzer, optical scrambler, monochromator, and CCD detector (Benevides *et al.*, 1993; Tsuboi and Thomas, 2007b). A thermoelectrically cooled sample stage is also advantageous. The success of the method depends ultimately upon achieving a known, uniform, and stable orientation of the sample molecules with respect to the directions of the electric vectors of the exciting and scattered radiation. Experimental techniques appropriate to Raman microspectroscopy of oriented viruses and their protein and nucleic acid constituents have been surveyed recently (Tsuboi and Thomas, 2007b).

We note that NIR lasers and NIR-optimized detectors are finding increasing use in commercial Raman spectrometers and microscopes. Often, it is desirable to compare the spectra collected using such instrumentation with spectra reported in the literature that were collected using excitation wavelengths in the visible region. It should be kept in mind that the relative intensities of bands in NIR-excited Raman spectra of proteins or nucleic acids may differ significantly from those observed in the corresponding spectra obtained using visible excitation wavelengths (Benevides, Overman and Thomas, 2005a).

13.5
Analysis of Raman Spectroscopic Data

13.5.1
General Considerations

Raman spectra of viral proteins and nucleic acids are usually collected repetitively, and the individual data collections are averaged to achieve an acceptable signal-to-noise ratio (∼10: 1 or greater). The length of each accumulation (exposure time) is dictated by the stability of the sample at the experimental conditions employed and the objective of the experiment. The raw data typically require one or more of the following refinement steps: (i) precise wavenumber calibration versus known standards (e.g. inert gas emission spectra and/or Raman spectra of organic liquids), (ii) removal of transient drift in the spectral baseline by polynomial fitting, (iii) elimination of scattering contributions from the silica glass capillary by spectral subtraction, (iv) elimination of detector artifacts caused by cosmic rays or spurious light reaching the CCD, and (v) normalization of the intensities of all exposures in the accumulation to the same ordinate scale. Artificial refinements of the data, such as the use of computational algorithms for smoothing of natural spectral noise, narrowing of natural spectral bandwidths, or reduction of spectral band overlap, should be scrupulously avoided. Whenever a series of spectra is processed, particular care must be taken to avoid introduction of any systematic errors (Benevides *et al.*, 2002; Movileanu, Benevides and Thomas, 2002a).

Quantitative analysis of the ordered secondary structures present in native proteins – specifically α-helix and β-strand conformations of the polypeptide chain – can be accomplished by decomposition of the prominent amide I (1640–1680 cm^{-1}) or amide III (1230–1310 cm^{-1}) bands of the Raman spectrum. Several approaches have been described (Asher *et al.*, 2001; Bandekar, 1992; Sane, Cramer and Przybycien, 1999; Williams, 1983) including decomposition of the amide I profile in terms of a relatively simple basis set (Berjot, Marx and Alix, 1987). Although the method of Berjot *et al.* is constrained by the limited reference data set upon which it is based (obtained mainly from spectra of small globular proteins), it is particularly useful for viral proteins and their assemblies, especially when quantifying a change in the structure. Fourier deconvolution of complex bands can also prove helpful in certain cases, although such methods should be used with caution and the results interpreted accordingly (Thomas and Agard, 1984).

Analysis of Raman spectral changes that reflect structural transformations or interactions of viral proteins and nucleic acids can be exploited to elucidate kinetic and thermodynamic parameters. Relevant applications have been described recently (Movileanu, Benevides and Thomas, 2002b; Tuma, Preveliage and Thomas, 1998b). More powerful approaches – based upon factor analysis (Malinowski, 2002) – offer greater sensitivity and selectivity, and improved insight into the structural basis of biomolecular interaction. Several equivalent algorithms are available to statistically treat large sets of Raman spectra, including principal component analysis (PCA) and singular value decomposition (SVD). The latter enables testing of specific theoretical models and provides quantitative parameters (Hanus *et al.*, 1999, 2004; Prochazka *et al.*, 2002). Physicochemical properties and structural information are derived simultaneously by SVD and can provide a comprehensive characterization of the system under investigation.

13.5.2
Singular value decomposition

Using the SVD algorithm, a series of N Raman spectra can be represented as $Y_i(\nu)$, where $i = 1, \ldots, N$ and ν is the number of data points in each spectrum. The set $Y_i(\nu)$ is transformed into a set of N orthonormal components (singular vectors) given as $S_j(\nu)$, where $j = 1, \ldots, N$. The vectors S_j decrease in statistical weight with increasing j. We express the statistical weights as W_j (singular values); the relative contribution of the jth component to the i-th Raman spectrum is expressed in terms of the unitary matrix V_{ij} by Eq. (1):

$$Y_i(\nu) = \sum_{j=1}^{N} W_j V_{ij} S_j(\nu) \qquad (1)$$

The series of N Raman spectra $[Y_i(\nu)]$ can be approximated within the experimental error(s) by a subset of $S_j (j = 1, 2, \ldots, M)$ components, where $M < N$. This value of M also represents the number of independent spectral species in the original series and constitutes the dimension of the factor analysis (Malinowski, 2002).

The SVD approach is illustrated in Figure 13.3 for a simple series of spectra, namely, the 28 spectra ($N = 28$) of Na_2SO_4 at two different concentrations (4 and 20 mM) in H_2O and as a function of temperature over the interval $11 < t < 70\,^{\circ}C$. Here, we have monitored the spectral interval 800–1200 cm^{-1} ($\nu = 400$), which includes the prominent 980 cm^{-1} band of the sulfate ion (symmetrical S–O stretching mode). The SVD analysis of Figure 13.3 shows that all of the spectral information is expressed by three independent spectral components $S_1(\nu)$, $S_2(\nu)$, $S_3(\nu)$. Thus, in this simple example, the number of independent species is identified as three ($M = 3$). In biomolecular systems the number of independent species is usually not known and the determination of factor dimension by SVD can be crucial. In such cases, the corresponding SVD analysis can also provide information of direct physicochemical significance, as will be illustrated by an example below (see Section 13.7.2.2).

An important and convenient criterion for determination of the factor dimension in the SVD analysis is the residual error between the parent spectra and those generated from the M subspectra. As long as an increase of M results in a better than linear decrease of the residual error, the additional subspectra describe significant and relevant spectral changes (Malinowski, 2002). Auxiliary criteria are: (i) randomness of the relative contributions to the original Raman spectra (rows of the matrix V_{ij}), (ii) signal-to-noise ratio in the subspectrum $S_j(\nu)$, and (iii) singular value W_j. The factor dimension can, however, exceed the number of genuine spectral components owing to the presence of various artifacts in the Raman spectra. Typical artifacts may be (i) nonuniform background correction within the series, (ii) wavenumber scale drift, or (iii) traces of parasitic signals, such as the contributions from the glass capillary cell. Exceptional care must therefore be taken to eliminate all artifacts during the processing of the spectral series.

Overall, SVD accomplishes a substantial reduction in the size of the experimental data set, generally from many experimentally obtained spectra (N) to a few computed subspectra (M). Fitting of a theoretical model leads to additional data reduction (elimination of the spectral components). In effect, the model is applied only to the relevant columns of the matrix V_{ij} multiplied by their corresponding singular values W_j (Hanus *et al.*, 1999, 2004; Prochazka *et al.*, 2002).

13.5.3
Interpretation of Polarized Raman Spectra

Up to the present, polarized Raman spectroscopy has not been widely used to study protein structures. This is due in part to the difficulty of determining the orientations of protein molecules and their subgroups in macroscopic samples suited for polarized Raman analysis, and in part to the complexity of interpreting the polarized Raman scattering. Raman

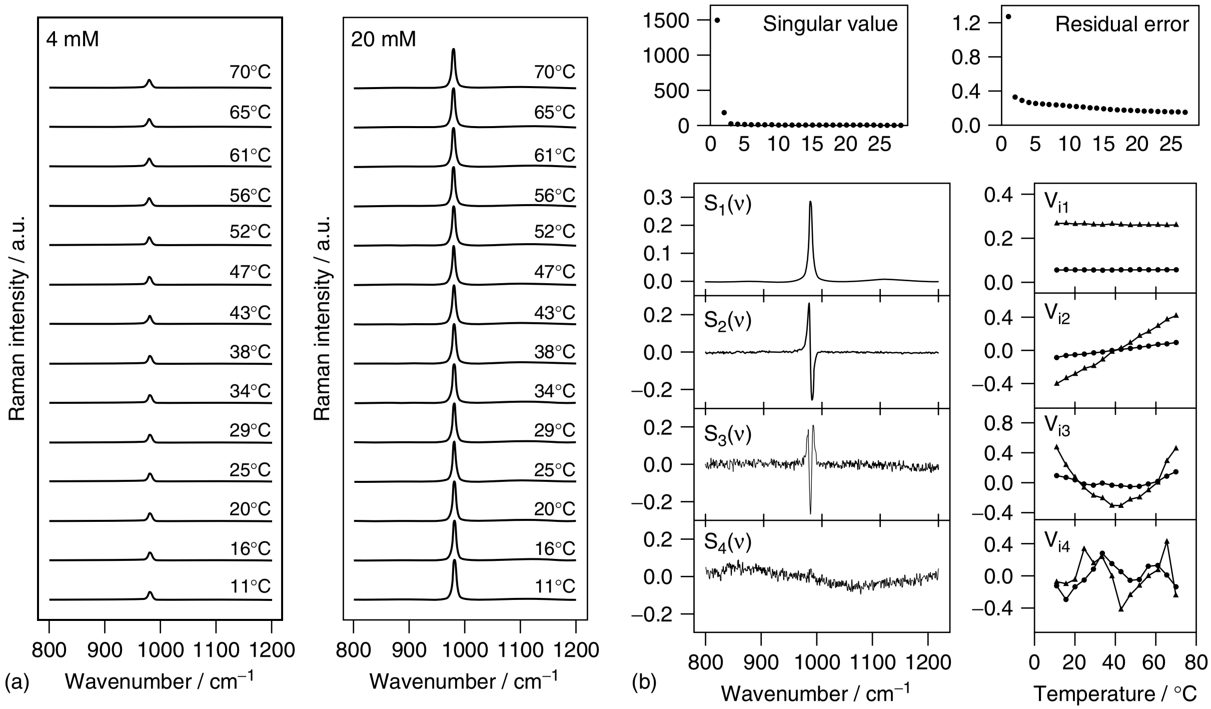

Fig. 13.3 (a) A series of Raman spectra showing the symmetrical stretching band of the sulfate ion (SO_4^{-2}) near 980 cm^{-1}. Data were obtained from solutions of Na_2SO_4 (4 and 20 mM) over the temperature range $11 < t < 70\,°C$, as labeled. (b) Factor analysis treatment of the spectral series using the SVD algorithm and showing singular value (upper left), singular vectors with the highest singular values $S_1(\nu)$, $S_2(\nu)$, $S_3(\nu)$, and $S_4(\nu)$ (lower left panel), parameter-dependent distribution of the singular vectors V_{i1}, V_{i2}, V_{i3}, and V_{i4} (lower right), and residual error (upper right). The vector $S_1(\nu)$ represents a weighted average spectrum of the series, where contributions V_{i1} reflect the higher intensity of the 980 cm^{-1} band in the more concentrated solution (▲). The singular vectors $S_2(\nu)$, $S_3(\nu)$, and $S_4(\nu)$ represent linearly independent spectral changes of, respectively, decreasing statistical importance. $S_2(\nu)$ shows the shift of the 980 cm^{-1} band to lower wavenumber with increasing t; $S_3(\nu)$ shows the corresponding broadening; and S_4 (and other vectors not shown) represent random noise in the data. Relative contributions of the significant singular vectors to the original Raman spectra are expressed in the V_{i1}, V_{i2}, and V_{i3} scores, respectively.

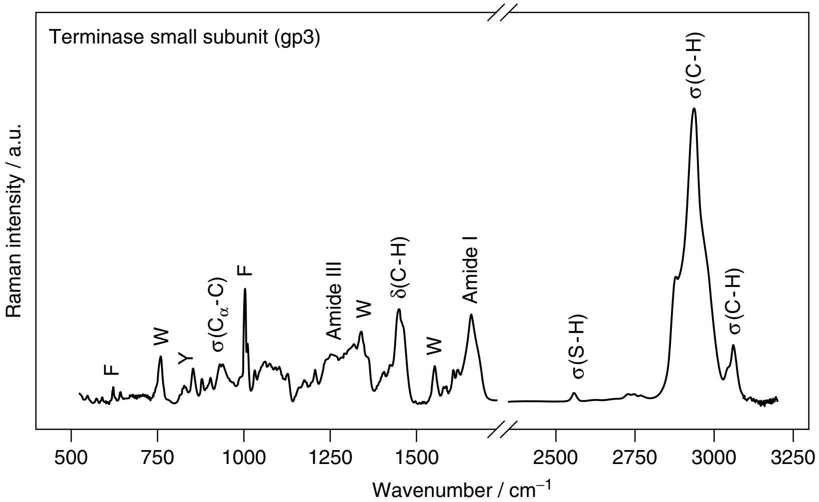

Fig. 13.4 Raman signature of the terminase small subunit (gp3) of bacteriophage P22. The spectrum is divided into: (i) the region 520–1750 cm^{-1}, where the often utilized amide modes of the polypeptide main chain and skeletal stretching and bending modes of the side chains predominate, and (ii) the often neglected region 2300–3200 cm^{-1}, where hydrogenic stretching modes of cysteinyl SH and aliphatic and aromatic CH groups occur. Assignments for many prominent peaks are shown. Labels indicate stretching (σ) and bending (δ) modes of specific bonds or assigned side chain markers (1-letter amino acid abbreviations). See also Table 13.1.

anisotropy is defined by a set of relative spectral intensities, I_{jk}, for which the indices j and k refer to a rectangular coordinate system (*abc*) that is fixed to the protein sample, such that j and k represent, respectively, the directions of the incident and Raman scattered electric vectors. Measurement and interpretation of the complete set of Raman intensities I_{aa}, I_{bb}, I_{cc}, I_{ab}, I_{bc} and I_{ca}, can represent a formidable challenge.

13.6
Characteristics of Raman Spectra of Viral Proteins and Nucleic Acids

The structural interpretation of Raman and UVRR spectra of viral proteins and nucleic acids requires definitive spectral band assignments. The considerable progress achieved in this area has been reviewed elsewhere (Austin, Jordan and Spiro, 1993; Benevides, Overman and Thomas, 2005a, 2005b; Miura and Thomas, 1995a; Tsuboi and Thomas, 2007b; Tuma and Thomas, 2002; Tuma, 2005). In summary, the required definitive assignments can be achieved by diverse approaches, including: (i) comparison of Raman wavenumbers and intensities with corresponding infrared spectral data; (ii) determination of spectral wavenumber shifts accompanying stable isotope substitutions, usually $^{1}H \rightarrow {}^{2}H$ (D), $^{12}C \rightarrow {}^{13}C$, $^{16}O \rightarrow {}^{18}O$, or $^{14}N \rightarrow {}^{15}N$; (iii) effects of pH, temperature, and/or environmental parameters on the Raman and infrared spectra; (iv) detailed and well analyzed Raman and infrared spectra of simpler molecules, which are structurally related

Tab. 1 Raman wavenumbers and assignments for the prominent bands in spectra of H_2O and D_2O solutions of proteins (Benevides *et al.*, 2004; Overman and Thomas, 1999; Tuma *et al.*, 1998a)

Wavenumber (cm^{-1})[a] H_2O	D_2O	Assignment[b]
621	621	Phe
643	642	Tyr
699	–	amide V
722	722	Met, Tyr, δ(C–C–C)
758	754	Trp, Ala
825	825	Tyr (Fermi doublet)
850	850	Tyr (Fermi doublet)
877	–	Trp
897	887	Lys, Arg, Ala
–	910	amide III′, side-chains
–	927	amide III′ (β-strand)
934	–	ν(C^α-C^β) (α-helix)
–	950	amide III′ (α-helix)
957	–	Val. Leu, δ(CH_3)
–	963	amide III′ (coil)
–	992	amide III′ (extended conformation)
1003	1003	Phe
1012	–	Trp
1032	1032	Phe
1060	–	Lys, Arg, Ala, ν(C–C, C–O)
1081	–	Lys, ν(C–N)
1101	–	Pro, Ala, ν(C^α–N), ν(C–C)
1127	–	Trp, ν(C–C), ν(C–N)
1156	–	δ(CH_3)
1174	1174	Tyr, δ(CH_3)
1206	1206	Tyr, Phe, Trp
1230–1240	–	amide III (β-strand)
1245–1255	–	amide III (coils, turns)
1264–1272	–	amide III (α-helix)
1264	1260	Tyr
1300	–	amide III (α-helix)
1318	1318	δ(CH_2)
1340	–	Trp (Fermi doublet), δ(C–H)
1358	–	Trp (Fermi doublet), δ(C–H)

1605	1608	Phe, Tyr
1618	1614	Tyr, Trp
1645–1654	1633–1640	amide I/I′ (α-helix)
1665–1674	1655	amide I/I′ (β-strand)
1660–1665	–	amide I (coil)
1684	1669	amide I/I′ (extended conformation)

[a] Wavenumber values are believed accurate to ±1 cm^{-1}.

[b] Abbreviations: ν, stretching vibration; δ deformation vibration.

to the viral protein or nucleic acid; (v) Raman analyses of single crystals of related molecules, the structures of which have been authenticated by X-ray diffraction analysis, or analysis of corresponding solution data obtained by high-resolution NMR methods; (vi) *ab initio* calculations of intramolecular force fields and normal coordinate calculations based upon them; (vii) depolarization ratios of the Raman bands for randomly oriented molecules; (viii) polarized Raman measurements on oriented fibers or single crystals, and (ix) Raman excitation profiles, which correlate Raman intensities with laser excitation wavelengths.

Generally, Raman spectra of viral proteins are dominated by localized vibrations of multiply bonded atoms, such as the amide vibrational modes (amide I and amide III) associated with the peptide group ($C^{\alpha}-NH-C{=}O$) and aromatic ring modes associated with the amino acid side chains of tyrosine (Tyr), tryptophan (Trp), and phenylalanine (Phe). The sulfhydryl (S–H) stretching mode of cysteine (Cys) is also a significant contributor. Conversely, contributions from vibrational modes of nonaromatic side chains are generally weak. However, when the numbers of such side chains are large, their cumulative contributions can be significant. Additionally, chemical groups that are common to many side chains, such as the $C^{\beta}H_2$ moiety, can contribute importantly to the protein Raman spectrum (Overman and Thomas, 1999). Prominent bands represented in Raman spectra of H_2O and D_2O solutions of most viral proteins and their corresponding group assignments are summarized in Table 13.1.

Raman spectra of viral nucleic acids (DNA and RNA) are similarly dominated by spectral bands attributable to ring vibrations involving multiply bonded atoms of the purine and pyrimidine nucleotide bases (A, T or U, G, C). Symmetrical stretching modes of the phosphodiester (C–O–P–O–C) and phosphodioxy (O–P=O) linkages of the sugar–phosphate backbone are also major contributors (Thomas and Tsuboi, 1993). By comparison, the vibrational modes of the furanosyl methylenes in the deoxyribosyl (DNA) or ribosyl (RNA) sugars lead to feeble Raman scattering. However, as noted above for the aliphatic groups of nonaromatic amino acid side chains in proteins, the intrinsically weak Raman scattering of the furanosyl groups can achieve prominence in the spectra of DNA or RNA because of the relatively large numbers of such groups represented in the nucleic acid chain. Prominent bands in the Raman spectrum of DNA have been listed in previous surveys (Benevides, Overman and Thomas, 2005b; Thomas, 1999; Tuma and Thomas, 2002).

13.6.1
The Protein Raman Spectrum

13.6.1.1 Raman Markers of Main Chain Conformation: Amide I and Amide III Modes

The Raman spectrum of a specific viral protein, the terminase small subunit (gp3) of bacteriophage P22, is shown in Figure 13.4. Assignments for the most prominent spectral bands of gp3 correspond to the listing given in Table 13.1. The dominating amide I and amide III markers, which occur respectively in the intervals 1640–1680 cm^{-1} and 1225–1320 cm^{-1} (Bandekar, 1992; Chen and Lord, 1974a; Lippert, 1976; Miura and Thomas, 1995a; Thomas, Prescott and Urry, 1987; Yu, Lippert and Peticolas, 1973), are particularly useful as quantitative indicators of protein secondary structure (Berjot, Marx and Alix, 1987; Williams, 1983). Deuteration effects on these amide markers, which shifts them respectively to circa 1630–1670 cm^{-1} (designated amide I′) and circa 900–1000 cm^{-1} (amide III′) have also been profitably exploited (Thomas and Day, 1981; Tuma and Thomas, 1997; Williams *et al.*, 1980).

In addition to the amide I/I′ and amide III/III′ markers, other conformation-sensitive bands have been identified in Raman spectra of peptide model compounds and proteins. For example, vibrations localized in the peptide main chain near 950 and 1330 cm^{-1}, although not considered amide modes, are sensitive quantifiers of α-helix content (Benevides *et al.*, 2004; Tsuboi *et al.*, 2000). The amide II′ mode (circa 1400–1500 cm^{-1}), which involves peptide C–N stretching and achieves prominence only in spectra of deuterated proteins, can also be exploited for conformational analyses (Tuma *et al.*, 1996a; Tuma, Prevelige and Thomas, 1998b).

Because all Raman amide modes typically undergo significant and well-characterized wavenumber shifts with peptide group deuteration (NH → ND), they are conveniently exploited as probes of main chain dynamics as well as conformation (Tuma and Thomas, 1997; Tuma, Prevelige and Thomas, 1998b).

13.6.1.2 **Raman Markers of Side Chains**

Raman bands of tryptophan have been investigated extensively and many useful structural correlations have been developed for tryptophan side chains in proteins (Combs *et al.*, 2005; Harada, Miura and Takeuchi, 1986; Miura, Takeuchi and Harada, 1988, 1989; Takeuchi and Harada, 1986; Takeuchi, 2003). The intense and sharp tryptophan marker in the interval 1540–1560 cm^{-1} is indicative of the magnitude of the indolyl side chain torsion angle $\chi^{2,1}$ ($C^{\delta1}-C^{\gamma}-C^{\beta}-C^{\alpha}$). The tryptophan Fermi doublet with components at 1340 and 1360 cm^{-1} reflects the local environment of the indolyl ring, such that the intensity ratio I_{1360}/I_{1340} increases with increasing hydrophobicity. The tryptophan marker near 875 cm^{-1} is somewhat sensitive to indolyl NH hydrogen bonding. Strong N–H···X interactions lead to a band center near 871 cm^{-1}, while a hydrophobic environment shifts the band center to 883 cm^{-1}. The breathing vibration of the indolyl ring generates a tryptophan marker near 755 cm^{-1}, the intensity of which has been considered inversely related to the hydrophobicity of the local ring environment. Typically, the band intensity increases with decreasing hydrophobicity of the indolyl ring environment. Assignments, deuteration effects, and structural interpretations for tryptophan markers have been discussed in greater detail by Takeuchi (2003). Recently, the Raman markers associated with a nonhydrogen-bonding environment for the tryptophan side chain were inferred from a comprehensive vibrational analysis of the indolyl moiety in the gas phase (Combs *et al.*, 2005).

It has long been recognized that the *para*-substituted phenyl ring of tyrosine can generate a pair of relatively intense Raman bands near 830 and 850 cm^{-1} that corresponds to a Fermi interaction doublet (Lord and Yu, 1970a; Siamwiza *et al.*, 1975). The correlation between the ratio of intensities of the doublet components (I_{850}/I_{830}) and the hydrogen-bonding state of the phenolic OH group, which was initially quantified by Siamwiza *et al.* (1975) and later extended to the nonhydrogen-bonded phenoxyl state by Arp *et al.* (2001), is quite useful in viral protein applications (Overman *et al.*, 1994; Overman and Thomas, 1995; Tsuboi *et al.*, 2001, 2003a; Wen, Overman and Thomas, 1997). The doublet intensity distribution is governed by Fermi coupling between the phenolic ring-stretching fundamental expected near 840 cm^{-1} and the first overtone of the phenolic ring deformation mode occurring near 420 cm^{-1}, such that the following intensity distribution applies: (i) If the tyrosine phenoxyl group functions as a strong hydrogen-bond donor only, then $I_{850}/I_{830} = 0.30$, (ii) if the phenoxyl group functions as both a donor and an acceptor, then $I_{850}/I_{830} = 1.25$, (iii) if the phenoxyl group functions as a strong hydrogen-bond acceptor only, then $I_{850}/I_{830} = 2.5$, and (iv) if the phenoxyl group is not hydrogen bonded, then $I_{850}/I_{830} = 6.7$. For a protein containing a single tyrosine, the I_{850}/I_{830} ratio is unambiguously interpretable. Conversely, if the protein contains multiple tyrosines, then the observed I_{850}/I_{830} reflects the average hydrogen-bonding state of all tyrosine phenoxyls. In the latter eventuality, site-directed isotopic substitutions or mutagenesis can be exploited to deduce the hydrogen-bonding states of individual tyrosyl residues (Overman *et al.*, 1994). The nonhydrogen-bonded phenoxyl state, although unlikely to occur for tyrosines either within folded globular proteins or at solvent-exposed protein surfaces, is often encountered in the tightly packed α-helical subunits of filamentous virus capsids (Arp *et al.*, 2001; Overman *et al.*, 1994; Overman and Thomas, 1995).

The Raman band resulting from the cysteine sulfhydryl bond (S–H) stretching vibration is a unique probe of the local S–H structure and dynamics of the cysteine side chain (Li and Thomas, 1991; Li, Wurrey and Thomas, 1992a; Tuma *et al.*, 1993). The sulfhydryl Raman marker occurs in a region of the spectrum (2500–2600 cm^{-1}) that is virtually devoid of interference from any other Raman band of a protein or its aqueous solvent. The relatively large Raman cross-section associated with the S–H stretching mode and the sensitivity of the bond stretching vibration to hydrogen-bonding interactions and side chain conformation are well documented. Specific correlations have been established between the strength of sulfhydryl hydrogen bonding to an appropriate acceptor atom ($\text{S–H}\cdots\text{X}$ bonding) and the wavenumber of the S–H bond stretching vibration (Li and Thomas, 1991; Li, Wurrey and Thomas, 1992a). The stoichiometric dependence of the S–H Raman band on thiol concentration also confers a unique spectrophotometric value on the S–H marker for assessing the pK_a values of thiol/thiolate equilibria (Li *et al.*, 1993a; Vohnik *et al.*, 1998). Because the S–H marker requires the reduced state of cysteine, it can also prove useful for distinguishing this state from its oxidized counterpart, cystine, when either is possible in a protein.

Raman bands originating from bond stretching vibrations of the disulfide network of cystine ($\text{C}^{\alpha}\text{–C}^{\beta}\text{–S–S–C}^{\beta}\text{–C}^{\alpha}$) have been considered in detail (Lord and Yu, 1970a, 1970b; Sugeta, 1975; Van Wart *et al.*, 1973; Van Wart and Scheraga, 1977, 1986b). Most useful is the disulfide (S–S) stretching marker that ordinarily occurs within the 450–550 cm^{-1} interval and is sensitive in wavenumber to the

$C^\beta-S-S-C^\beta$ dihedral angle (Van Wart and Scheraga, 1986a).

Raman bands of histidine and the histidinium ion are relatively weak compared to those of the aromatic amino acids (tyrosine, tryptophan, and phenylalanine). However, when the protein does not contain many aromatic residues, some histidine bands can be identified. At neutral pH, the Raman spectrum of the imidazolium ring of histidine exhibits several weak bands, whereas at acidic pH, their Raman intensities are redistributed to fewer bands of intermediate intensities. In its deuterio form, the imidizolium ring exhibits a relatively strong band at 1408 cm^{-1}, which has been assigned to the $N_1-C_2-N_3$ symmetric stretch (Tasumi *et al.*, 1982). The band is particularly useful for monitoring histidine H/D exchange dynamics as well as histidine–histidinium equilibria in D_2O (Harada *et al.*, 1982; Okada, Miura and Takeuchi, 2003). A linear correlation between the wavenumber of the 1408 cm^{-1} Raman band and the histidine side chain conformation has been proposed (Takeuchi *et al.*, 1991; Takeuchi, 2003). The histidine markers are also sensitive to the binding of transition metals at imidazole sites and the Raman spectrum has been extensively exploited for monitoring such interactions (Miura *et al.*, 1998; Takeuchi, 2003).

13.6.2
The Nucleic Acid Raman Spectrum

The concept of localized group frequencies, as referred to above, may break down in biological macromolecules as a consequence of mechanical coupling between vibrational modes of covalently linked groups. Although this phenomenon is rarely encountered in Raman spectra of proteins, it occurs often in Raman spectra of nucleic acids – in the form of coupling between modes of the nucleotide purine or pyrimidine bases [adenine (A), cytosine (C), guanine (G), and thymine (T)] and those of the sugar–phosphate moiety. The resulting delocalized vibrational modes may then generate Raman bands that combine the relatively high intensity typical of localized purine and pyrimidine vibrational modes with the conformational dependency expected of modes associated with the sugar–phosphate backbone. Several such Raman bands have been identified for both DNA and RNA (Erfurth, Kiser and Peticolas, 1972; Thomas, Medeiros and Hartman, 1971). These Raman bands manifest dependence of wavenumber and/or intensity upon the nucleic acid macromolecular conformation (secondary structure) and are often referred to as Raman conformation markers.

Two categories of Raman conformation markers have been delineated (Thomas and Wang, 1988b), those relating to the overall conformation of the sugar–phosphate backbone and those relating to the conformation of the constituent nucleosides. The former are sensitive primarily to changes in the torsions of the phosphodiester bond network of the backbone ($-P-O5'-C5'-C4'-C3'-O3'-P-$), but do not depend strongly upon the identity of the attached base. These are listed in Table 13.2. Thus, the occurrence of unique backbone conformation markers for the three known secondary structures of DNA, that is *Z* DNA (745 ± 3 cm^{-1}), *A* DNA (807 ± 3 cm^{-1}) and *B* DNA (835 ± 7 cm^{-1}), facilitates the use of Raman spectroscopy to distinguish the

Tab. 2 Raman bands diagnostic of the *A*, *B* and *Z* backbone conformations of double-stranded DNA[a].

Mode type	*A* DNA	*B* DNA	*Z* DNA
σ(C–O)	706 ± 5		
σ_{sym}(O–P–O)	807 ± 3[b]	790 ± 5	745 ± 3
σ_{sym}(O–P–O)		835 ± 7[c]	
σ_{sym}(PO_2^-)	1099 ± 1	1092 ± 1	1095 ± 2
δ(C2′H_2)	1418 ± 2	1420 ± 2	1425 ± 2

[a] Wavenumbers (cm^{-1} units) are determined from Raman spectra of DNA crystals and fibers of known structure. Abbreviations: σ, stretching; sym, symmetric; δ, deformation.

[b] The corresponding band in *A* RNA is observed at 813 ± 2 cm^{-1}.

[c] In *B* DNA containing both GC and AT pairs, the band is broad and centered close to 835 cm^{-1}. In *B* DNA containing only GC or only AT pairs, the band is sharp and centered, respectively, close to 830 or 840 cm^{-1}.

A, *B*, and *Z* conformations from one another. The relatively large range quoted in Table 13.2 for the *B* marker (±7 cm^{-1}) reflects the structural complexity of *B* DNA in comparison to *A* and *Z* DNAs. In fact, the diversity of Raman markers observed for *B* DNAs of different base composition suggests a family of structures, the precise conformations of which are dependent upon the A–T and G–C base-pair content and sequence. Thus, regions of *B* DNA containing predominantly G–C and C–G base pairs exhibit the *B* marker near 830 cm^{-1}, while those containing predominantly A–T and T–A pairs exhibit the marker near 840 cm^{-1}. This distinction is believed due to the slightly different phosphodiester torsions associated with the groove dimensions of G–C/C–G rich (narrow minor groove) and A–T/T–A rich (wide minor groove) sequences. Consistent with this finding is a resultant broad band centered near 835 cm^{-1} in DNAs containing comparable percentages of G–C/C–G and A–T/T–A pairs.

Nucleoside conformation markers, on the other hand, originate primarily from certain base ring-stretching vibrations that are weakly coupled via the glycosyl bond to motions of the furanose ring atoms. These are listed in Table 13.3. For each nucleoside listed the markers are sensitive to either furanose pucker, as measured by torsion angle δ (defined by atoms C5′–C4′–C3′–O3′ of the sugar), or glycosyl orientation, as measured by the torsion angle χ (defined by atoms O4′–C1′–N1–C2 or O4′–C1′–N9–C4 for pyrimidine or purine nucleosides, respectively), or both.

These considerations apply also to RNA, with the important distinctions that the base uracil (U) replaces thymine (T) and the sugar ribose replaces deoxyribose. Importantly, only one type of secondary structure occurs for double-stranded RNA, namely *A* RNA, which exhibits many architectural and spectroscopic similarities to *A* DNA.

The following additional generalizations can be made regarding relative Raman band intensities of the nucleic acid constituents: (i) In-plane stretching vibrations of conjugated CC, CN, and CO double bonds of the bases yield

Tab. 3 Raman bands diagnostic of the conformations of deoxynucleosides and nucleosides of nucleic acids[a].

Residue	C3′ endo/anti	C2′ endo/anti	C3′ endo/syn	C2′ endo/syn
G	664 ± 2[b]	682 ± 2	625 ± 3	671 ± 2
	1318 ± 2	1333 ± 3[c]	1316 ± 2	1324 ± 2
A	644 ± 4	663 ± 2	624 ± 3	
	1335 ± 2	1339 ± 2	1310 ± 5	
C	780 ± 2	782 ± 2	784 ± 2	
	1252 ± 2	1255 ± 5	1265 ± 2	
T	642 ± 2	665 ± 2		
	745 ± 2	748 ± 2		
	777 ± 2	790 ± 3		
	1239 ± 2	1208 ± 2		

[a] Wavenumbers (cm^{-1} units) are determined from Raman spectra of DNA crystals and fibers of known structure.
[b] The corresponding band in structures containing rG is usually observed at 668 ± 1 cm^{-1}.
[c] A weak companion band near 1316 cm^{-1} is also observed in *B* DNA.

Raman bands of the highest intensity. Conversely, out-of-plane ring vibrations yield relatively weak bands (Lord and Thomas, 1967a). (ii) Symmetrical stretching vibrations of the diesterified orthophosphate moiety, namely phosphodioxy (PO_2^-) and phosphodiester (C–O–P–O–C) group vibrations, generate intense Raman bands. On the other hand, antisymmetrical and asymmetrical modes of the orthophosphate moiety are usually too weak to be observed (Shimanouchi, Tsuboi and Kyogoku, 1964). (iii) Vibrations localized in the sugar moieties of DNA (deoxyribose) or RNA (ribose) exhibit very low Raman intensities, unless as noted above, they are coupled to modes of the bases (Erfurth, Kiser and Peticolas, 1972; Lord and Thomas, 1967a; Shimanouchi, Tsuboi and Kyogoku, 1964; Thomas and Hartman, 1973). (iv) On the basis of Raman excitation profiles reported by several groups (Austin, Jordan and Spiro, 1993; Blazej and Peticolas, 1977; Kubasek, Hudson and Peticolas, 1985; Tsuboi, Nishimura and Hirakawa, 1987; Ziegler, 1984), UVRR intensities of the nucleic acid bases are generally greatest when excitation wavelengths in the vicinity of 260 nm are employed. Sugar and phosphate group vibrations are absent from UVRR spectra excited at wavelengths in the range 200–300 nm (Wen and Thomas, 1998).

13.7
Applications

13.7.1
Assembly and Maturation of the Bacteriophage P22 Capsid

The shell of bacteriophage P22 is constructed from 420 copies of a 47-kDa coat protein subunit (gp5) (see also Figure 13.1). Raman spectroscopy has provided details of the self-assembly of gp5 into the viral shell precursor (procapsid) and the subsequent rearrangement of the subunits of the procapsid shell to form the architecture of the mature capsid lattice (Prevelige *et al.*, 1993; Tuma and Thomas, 1997; Tuma, Prevelige and Thomas, 1998b; Tuma *et al.*, 2001). Structural characterization of the initial assembly step, that is, the formation of the procapsid shell from gp5 monomers was made possible by improvements in the sensitivity of Raman instrumentation that allow acquisition of spectra of the monomer at very low concentration (Tuma *et al.*, 2001). Although Raman signatures of gp5 in the monomeric and procapsid shell states share many features, it is clear that procapsid assembly significantly perturbs the structure of the unassembled monomer (Figure 13.5). The computed difference spectrum, as shown in the bottom trace of Figure 13.5, highlights the spectral changes accompanying monomer-to-procapsid assembly. Importantly, the center of the Raman amide I marker is shifted from 1667 cm^{-1} in the monomer to 1663 cm^{-1} in the procapsid shell. This shift gives rise to the Raman difference peaks observed at 1655 cm^{-1} (assigned to α-helix) and 1673 cm^{-1} (β-strand) and corresponding troughs at lower and higher wavenumber values. The difference band pattern reflects a more ordered secondary structure for the subunit in the viral shell than in the monomer at the expense of disordered chain segments. The more highly ordered secondary structure of the shell subunit is confirmed in the difference spectrum in Figure 13.5, by the diminished

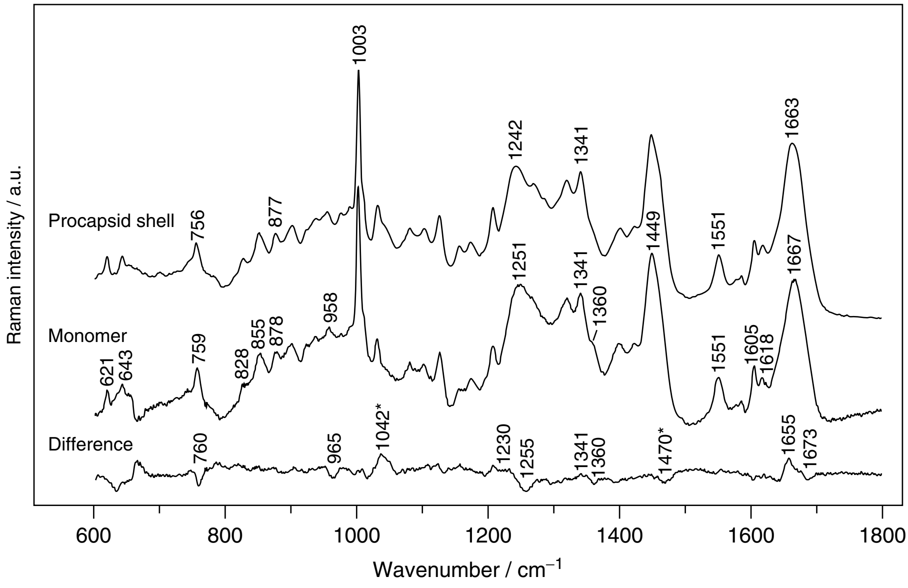

Fig. 13.5 Raman characterization of *in vitro* assembly of the bacteriophage P22 procapsid. Data were obtained with 514 nm excitation at low gp5 concentration (~15 μg/μL) and temperature (~10 °C) (Tuma *et al.*, 2001). The spectral difference profile (bottom trace) between gp5 monomer (middle trace) and shell (top trace) is modest. The amide band peaks and troughs reflect only minor reordering of the polypeptide backbone. Other different features are relatively small but significant, consistent with coupling between subunit folding and assembly. The monomer fold is, nevertheless, largely conserved with shell assembly.

intensity of the Raman amide III band of the monomer (1251 cm^{-1} band center), which leads to a difference trough at 1255 cm^{-1} (diminished irregular chain conformation) and difference peak at 1230 cm^{-1} (enhanced β-strand). These results show that the polypeptide backbone of the gp5 monomer undergoes refolding during procapsid assembly. Overall, about $4 \pm 1\%$ of the backbone, or 17 of 428 peptide bonds, are estimated to undergo refolding. Thus, assembly of the P22 procapsid leads to local reordering of a small but significant percentage of the peptide residues and demonstrates limited coupling of subunit folding with the shell assembly process. The native fold of the gp5 subunit is thus largely conserved with procapsid assembly.

In addition to the changes in subunit secondary structure noted above, the Raman spectrum also provides information on the effect of procapsid assembly on subunit tertiary structure. For example, the shift of the tryptophan (Trp) marker band at 760 cm^{-1} in the monomer to 756 cm^{-1} in the procapsid shell with a concomitant large decrease in intensity signifies a change in the amphipathic environment of the average Trp side chain. Broadening of the 1360 cm^{-1} component of the Trp Fermi doublet indicates that this change is due to a more hydrophilic indolyl environment in the procapsid shell subunit. Overall, the change in average Trp environment is small. Additional Raman markers show that the cysteine (Cys) sulfhydryl and tyrosine (Tyr) phenoxyl hydrogen-bonding environments are essentially invariant to the assembly process. Thus, despite measurable refolding of the coat protein backbone with procapsid assembly, the tertiary structure of the subunit is not greatly affected (Tuma *et al.*, 2001).

The folding state of gp5 in the monomeric and procapsid shell states has also been characterized by deuterium exchange of peptide NH groups (Tuma *et al.*, 2001). Figure 13.6a compares Raman profiles of the exchanged ND groups (amide III′ region, 900–1000 cm^{-1}) of gp5 in monomeric and procapsid shell states, following exposure of each to D_2O (pD 7.8) under native conditions (2 °C for monomer and 10 °C for procapsid shell). Also shown is the amide III′ profile of a gp5 control in which all NH groups were exchanged by deuterium under denaturing conditions prior to refolding of the fully exchanged protein in native D_2O buffer. These data show that NH → ND exchange is more extensive in the monomer than in the procapsid shell subunits. In particular, greater amide III′ intensity is observed at 930–945 cm^{-1} assignable to deuterated α-helix (Overman and Thomas, 1998b; Yu, Lippert and Peticolas, 1973), at 960 cm^{-1} assignable to deuterated disordered peptides (Chen, Lord and Mendelsohn, 1974b; Chen and Lord, 1974a; Tuma, Prevelige and Thomas, 1998b), and at 980–990 cm^{-1} assignable to deuterated β-strand (Chen, Lord and Mendelsohn, 1974b; Chen and Lord, 1974a; Tuma, Prevelige and Thomas, 1998b; Yu, Lippert and Peticolas, 1973). The amide III′ exchange profile of the monomer indicates that the native fold of the monomer comprises both unprotected and protected residues in regions of α-helix, β-strand, and disordered secondary structures. Figure 13.6a also shows extensive exchange protection. Neither the monomer nor procapsid shell subunit undergoes complete NH → ND exchange of α-helical, β-stranded, or disordered regions. The data suggest

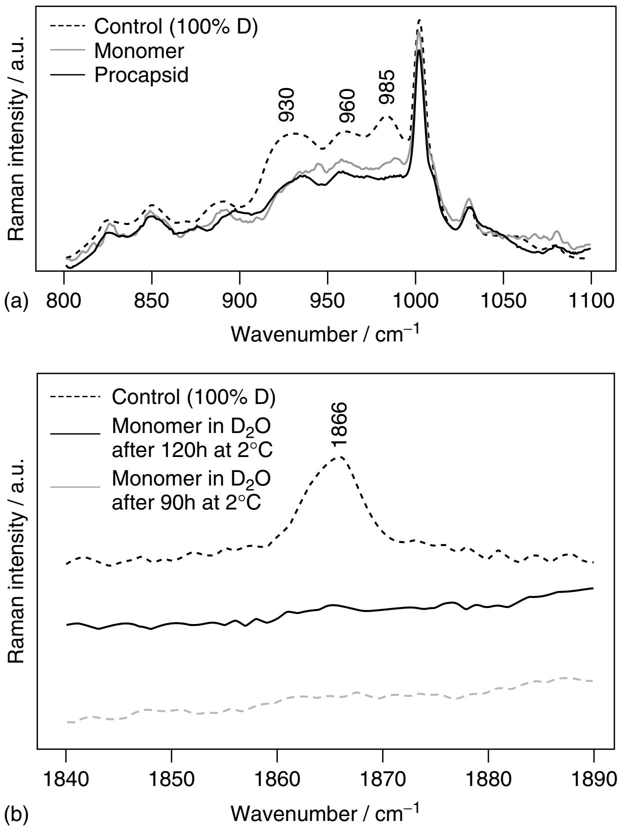

Fig. 13.6 Normalized Raman signatures (514 nm excitation) depicting native-state peptide NH $\rightarrow$ ND exchanges of P22 gp5 in the monomeric state (2 °C) and procapsid shell state (10 °C), each following 12 h exposure to D_2O buffer. (a) Amide III′ profiles of the P22 procapsid, native gp5 monomer and fully exchanged gp5 control. (b) Deuteriocysteinyl S–D stretching bands of the native gp5 monomer, following different conditions of exposure to D_2O (Tuma *et al.*, 2001).

that the most protected residues of the monomer are those located in regions of β-strand structure.

Raman-monitored H/D exchange of selected side chains can be used to identify residues of the protein folding core (Thomas, 1999). For example, the degree of protection of the S–H group of the single cysteine (Cys 405) in the coat protein is a measure of the accessibility of the *C*-terminal region to H/D exchange. Figure 13.6b depicts Raman spectra in the region 1840–1890 cm^{-1}, where the stretching vibration of the deuterated sulfhydryl group (S–D) is expected (Tuma *et al.*, 2001). The absence of an S–D band in the spectrum of the native gp5 monomer shows that the Cys 405 sulfhydryl is fully protected against H/D exchange. Protection persists for samples maintained at native conditions (pD 7.8, 2 °C) for up to 6 days. The S–H group can be exchanged only at conditions that favor global unfolding (40 °C). Thus, the Cys 405 sulfhydryl is buried within the hydrophobic folding core of the gp5 monomer. A similar degree of sulfhydryl exchange protection is observed when gp5 is assembled into the procapsid shell, but not upon maturation to the capsid shell (Tuma, Prevelige and Thomas, 1998b). This shows that the procapsid-to-capsid lattice transformation is accompanied by sequestering of the subunit *C*-terminal region from H/D exchange.

In summary, during P22 shell assembly about 20 peptide linkages of the gp5 monomer undergo local refolding without greatly affecting the global structure of the monomer. Compared to monomeric gp5, the procapsid subunits achieve enhanced protection against peptide H/D exchange. On the other hand, the monomer possesses a robust exchange-protected folding core that encompasses the Cys 405 sulfhydryl. Both the monomeric and procapsid states of the subunit constitute a distinct and compact late-folding intermediate, which ultimately matures to the native state of the capsid. Details of the additional changes in gp5 subunit structure and exchange protection that occur with the final procapsid → capsid lattice transformation (Figure 13.1) have also been quantified by Raman methods and are discussed in detail elsewhere (Tuma, Prevelige and Thomas, 1998b).

13.7.2
Assembly and Maturation of the Bacteriophage HK97 Head

13.7.2.1 Structural Considerations

The assembly pathway of the *E. coli* bacteriophage HK97, which differs fundamentally from that of P22, is shown schematically in Figure 13.7. Icosahedral structures of precursor (*prohead*) and mature (*head*) states of the bacteriophage HK97 shell have been determined by application of electron cryomicroscopy and X-ray crystallography to shells constructed *in vitro* from recombinantly expressed subunits (gp5, 42 kDa) (Wikoff *et al.*, 2000; Wikoff *et al.*, 2006). Mechanistic steps involving the initial assembly of the prohead (Prohead I), its transformation to Prohead II, and eventually its maturation to the Head are not well understood. Of particular interest is the

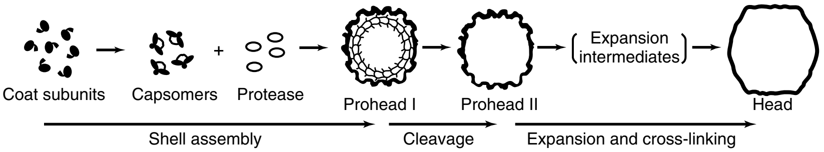

Fig. 13.7 Schematic representation of the *in vitro* assembly pathway of the icosahedral capsid of *E. coli* bacteriophage HK97. This pathway differs fundamentally from that of P22 (Figure 13.1) in that the precursor shell (Prohead I) is assembled from coat the protein monomer (gp5) via an oligomeric intermediate (capsomer) and without the participation of scaffolding protein subunits. Prohead I subsequently submits to a virally encoded protease that cleaves from gp5 the *N*-terminal domain (Δ-domain, residues 1–102) yielding the Prohead II shell. Subsequent shell expansion and subunit cross-linking generate the mature Head architecture (Benevides *et al.*, 2004; Hendrix and Duda, 1998).

structure and role of the gp5 *N*-terminal segment (Δ-domain, residues 1–102), which is cleaved from the Prohead I subunits by a virally encoded protease. This cleavage results in a reorganization of the shell lattice and the Prohead II architecture (Hendrix and Duda, 1998).

Raman spectra of Prohead I and Prohead II particles identify a conserved subunit domain with an α/β-fold, as well as a highly α-helical (74%) Δ-domain specific only to the Prohead I subunit (Figure 13.8a). The diagnostic tryptophan (1339 and 1551 cm^{-1}) and tyrosine (825 and 850 cm^{-1}) Raman markers are identical in subunits of both shells and indicate minimal changes in the tertiary structure of the *C*-terminal segment of gp5 (residues 104–385). However, a shift of the sulfhydryl Raman marker of Cys 362 from 2579 to 2573 cm^{-1} indicates a strengthening of the cysteinyl S–H···X bond with the prohead shell transformation (Benevides *et al.*, 2004).

The Raman signature of the Δ-domain was calculated by subtracting the Prohead II spectrum from the Prohead I spectrum (Figure 13.8b) (Benevides *et al.*, 2004). Interestingly, this difference spectrum exhibits a close correspondence to the Raman spectrum of the P22 scaffolding protein (Tuma and Thomas, 1997) and supports the notion that the Δ-domain fulfills a role in HK97 assembly similar to that of the scaffolding protein in P22 assembly. In contrast, the maturation of Prohead II to the Head involves a significant reordering of the secondary structure of gp5 (residues 104–385), as well as extensive changes in the subunit tertiary structure. The difference spectrum between the Prohead II and Head of HK97 (Figure 13.8c) demonstrates: (i) an increase in ordered secondary structure, (ii) altered interactions of tyrosine and tryptophan side chains, and (iii) additional strengthening of the S–H···X bond of the Cys 362 side chain.

13.7.2.2 Thermodynamic Properties of the Δ-Domain

Recently, Raman spectra of exceptional signal-to-noise quality were obtained from highly purified samples of Prohead I and Prohead II as a function of solution temperature in the interval 10–92 °C (Figure 13.9a and b). Quantitative analysis of the data allows elucidation of the thermostability of the Δ-domain within the framework of the prohead shell assembly pathway (Nemecek and Thomas, unpublished results). For both Prohead I and Prohead II, major spectral changes are observed between 85 and 92 °C, which can be attributed to thermal

Fig. 13.8 (a) Raman spectra of the HK97 Prohead I (top) and Prohead II (bottom) particles. The two spectra have been scaled to match the intensities of environment invariant tyrosine Raman markers at 642 cm^{-1}, as both particles contain the same number of tyrosine residues. (b) The Raman spectrum of the Δ-domain (bottom) obtained by subtracting the Raman spectrum of Prohead II from that of Prohead I. The intensity scale is expanded threefold over that shown in (a). The Raman signature of the P22 scaffolding protein (top), which is shown for comparison with that of the Δ-domain, reveals the fundamental similarities between the two protein structures. (c) Raman spectra of the HK97 mature Head (top) and Prohead II precursor (second from top), each normalized to the intensity of the 1449 cm^{-1} peak. The computed difference spectrum (bottom) is also shown (Benevides *et al.*, 2004).

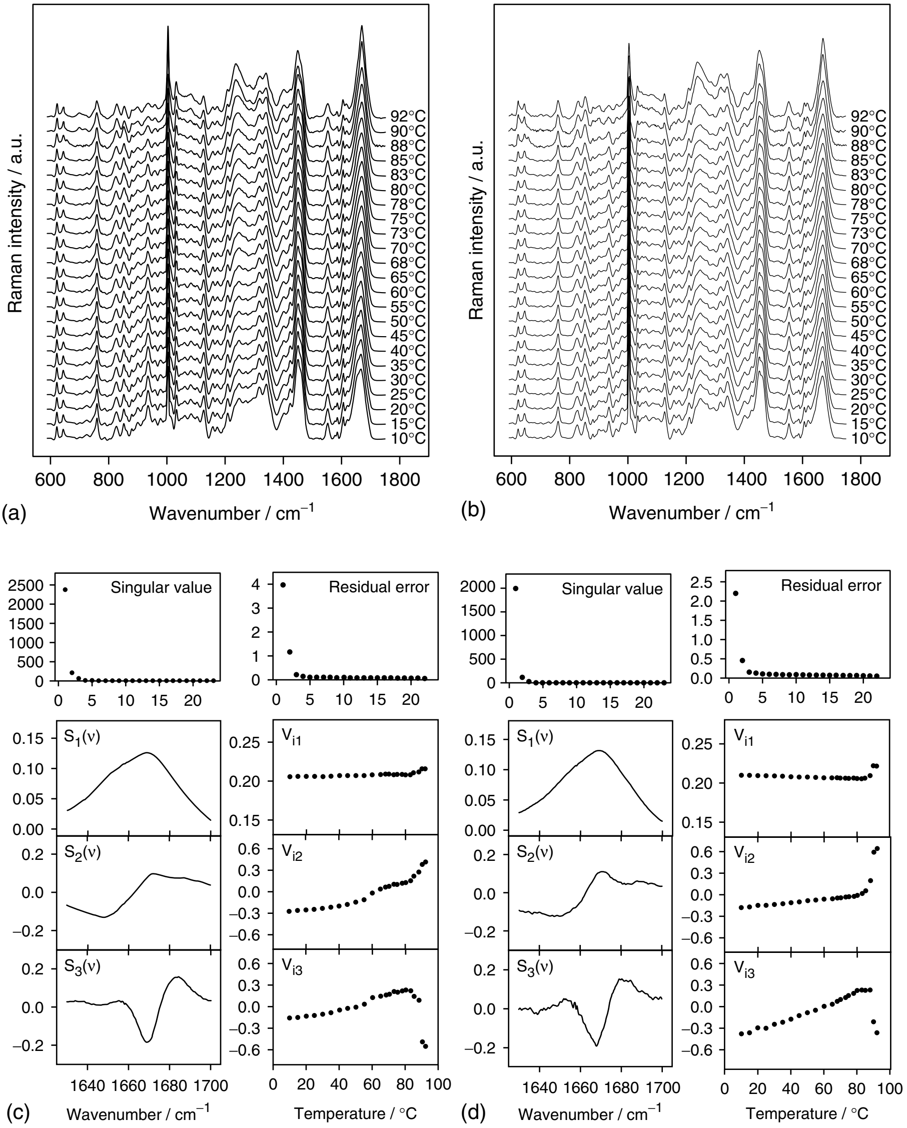

Fig. 13.9 Raman spectra of the bacteriophage HK97 Prohead I (a) and Prohead II (b) shells were collected over the temperature interval $10 < t < 92\,^\circ$C. Changes of secondary structure were analyzed by factor analysis (SVD algorithm) of the amide I conformational marker (1630–1700 cm^{-1}) of Prohead I (c) and Prohead II (d). Each spectral set can be described within the experimental noise level by three independent components. The scores V_{i2} of the second component manifest two distinct structural transitions in Prohead I, while Prohead II exhibits only one transition. For both Prohead I and Prohead II the high-temperature transition (~89 °C) corresponds to melting (thermal denaturation of the subunit). The lower temperature transition in Prohead I (~60 °C) represents unfolding of the Δ-domain.(Němeček and Thomas, manuscript in preparation).

denaturation of the subunits that are released upon shell disassembly. Spectral changes between 10 and 85 °C, on the other hand, reflect initial partial unfolding events in the shell subunits followed by the onset of shell disassembly. In the case of Prohead I, the observed changes include the effects of unfolding of the Δ-domain. The latter were deciphered and quantified by factor analysis of the Prohead I and Prohead II spectral series using the SVD algorithm. Figure 13.9c and d shows the factor analysis results for the amide I bands of Prohead I and Prohead II, inclusive of the third SVD component (i.e. V_{i3} terms). The contribution of the second component (V_{i2} term) to the respective parent spectrum reveals two sigmoidal transitions for Prohead I, but only a single transition for Prohead II. The first transition for Prohead I can be attributed to unfolding of the Δ-domain, while the second likely corresponds to Prohead I disassembly. Only the second transition is observed for Prohead II, consistent with the absence of the Δ-domain from the Prohead II subunit. Both parent spectral series can be approximated within the precision of the observed noise level by three spectral components $[S_1(\nu), S_2(\nu), S_3(\nu)]$. Consequently, each spectral series is said to contain three independent spectral species. For Prohead I, these are (i) the natively folded, (ii) Δ-domain unfolded, and (iii) globally unfolded shell subunit (residues 1–385). For Prohead II, these are (i) the natively folded, (ii) locally unfolded, and (iii) globally unfolded shell subunit (residues 104–385). Species (ii) of the Prohead II spectral series represents only a small structural change in comparison to that of species (ii) of Prohead I, which is reflected by a 50% smaller singular value of the second SVD component. Thermodynamic parameters that describe the stability of the Δ-domain in Prohead I were obtained by fitting V_{ij} scores of the significant components. A specific thermodynamic model for Δ-domain unfolding has been developed from these results (Nemecek *et al.*, 2008).

Raman spectra of the independent spectral species considered in the SVD analysis were also derived from the fitted parameters. It can be concluded from these studies that the Prohead I assembly confers structural thermostability on the Δ-domain and enhances the cooperativity of Δ-domain unfolding. This is accomplished by a secondary structural fold – specifically α-helix – that is converted to a β-strand conformation during Δ-domain unfolding. In a forthcoming publication these results will be further discussed (Nemecek *et al.*, 2008).

13.7.3

Structural Studies of Filamentous Bacteriophages

All filamentous bacteriophages are cylindrically shaped, flexible particles (~6 nm diameter and up to 2000 nm in length) that comprise an ss and covalently closed DNA genome packaged within a thin protein shell (capsid). The ssDNA molecule typically constitutes a small percentage (5–15%) of the total virion mass, while the capsid consists of a highly symmetrical arrangement of several thousand copies of a small subunit. The capsid of the filamentous bacteriophage Ff consists of approximately 2700 copies of the major coat protein (pVIII) and a few copies of minor proteins at the filament ends. Assembly of Ff takes place within the membrane of the *E. coli* host cell (Figure 13.2). The overall assembly architecture of Ff (strain fd) is depicted schematically in Figure 13.10 (bottom left panel). Also shown in Figure 13.10 is an electron micrograph of a single negatively stained fd particle (upper left panel) and a three-dimensional reconstruction of a small segment of the capsid surface, which was generated from images obtained by electron cryomicroscopy (right panel). Fiber X-ray diffraction and solid-state NMR studies of highly oriented specimens of fd provide useful information about the symmetry of the capsid subunit arrangement and are consistent with a predominantly α-helical secondary structure for the pVIII capsid subunit (Marvin *et al.*, 2006; Thiriot *et al.*, 2004; Zeri *et al.*, 2003).

Raman spectroscopy has been used extensively over the past several decades to probe further details of the molecular architectures of fd and other filamentous bacteriophages of the same (class I) and different (class II) capsid symmetries. Methods of off-resonance Raman, UVRR, and polarized Raman have all been exploited effectively for this purpose. Details of pVIII side chain orientations and hydrogen-bonding interactions, as well as information about the conformation and organization of the packaged ssDNA within the viral capsids have been obtained. Comprehensive surveys of the Raman studies of fd and other filamentous bacteriophages have been given elsewhere (Benevides, Overman and Thomas, 2005a; Tsuboi and Thomas, 2007b). Here, we consider a few representative applications.

13.7.3.1 Conformations of Packaged ssDNA

High resolution structural methods, such as X-ray crystallography and NMR solution spectroscopy, have not been applied successfully to the highly flexible filamentous virus particles. Additionally, the low DNA content of filamentous

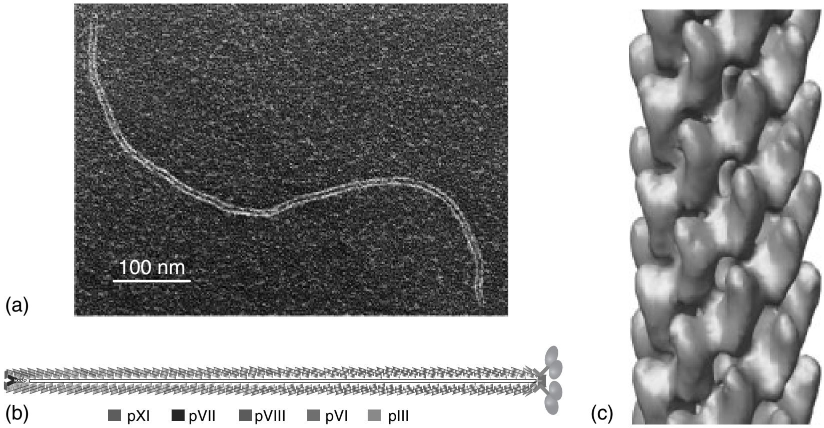

Fig. 13.10 The filamentous ssDNA bacteriophage fd. (a) A negatively stained electron micrograph showing one complete virion. The flexibility of the virion, which is apparent, is consistent with the experimentally determined equilibrium persistence length of 1.0 µm. (b) Cartoon of fd (not to scale) showing locations of the minor coat proteins. (c) Reconstruction of a 24 nm segment of fd at ~8 Å resolution from images obtained by electron cryomicroscopy (courtesy of E. H. Egelman, University of Virginia). (Please find a color version of this figure on the color plates.)

virions precludes definitive determination of conformational properties of the packaged ssDNA from available fiber X-ray diffraction and solid-state NMR data. Raman spectroscopy, on the other hand, provides a convenient approach for probing the structure and organization of the packaged ssDNA in filamentous viruses (Thomas and Murphy, 1975; Thomas *et al.*, 1988a). In the well-studied phages fd, Pf1, Pf3, and PH75, Raman markers of the deoxynucleosides (Tables 13.2 and 13.3) indicate, respectively, C3′-*endo*/*anti* (665 cm^{-1}) (Thomas *et al.*, 1988a; Wen, Overman and Thomas, 1997), C2′-*endo*/*anti* (682 cm^{-1}) (Thomas *et al.*, 1988a; Wen, Armstrong and Thomas, 1999), C3′-*endo*/*anti* (663 cm^{-1}) (Thomas *et al.*, 1988a; Wen *et al.*, 2001), and C2′-*endo*/*anti* (679 cm^{-1}) (Overman *et al.*, 2005) conformations. In a related application, interactions of packaged ssDNA genomes of fd and Pf1 with metal ions have also been probed by Raman methods (Day *et al.*, 1988).

In combination with the Raman tensors determined for local DNA vibrations (Thomas *et al.*, 1995), polarized Raman microspectroscopy has been applied to oriented fibers of the filamentous bacteriophages fd, Pf1, Pf3, and PH75 to reach conclusions about the orientations of ssDNA subgroups (Tsuboi *et al.*, 2003b, 2003a, 2005). The polarized Raman measurements show that while the bases of the packaged fd and Pf1 ssDNA genomes are nonrandomly oriented within their respective capsids, those of PH75 ssDNA lack uniformity of orientation (Benevides, Overman and Thomas, 2005b). Polarized Raman results on Pf1 DNA also show that the average DNA phosphodioxy group (PO_2^-) is oriented so that the line connecting the oxygen atoms ($O \cdots O$) forms an angle of 71° ± 5° with the virion axis (Tsuboi *et al.*, 2003a).

In the off-resonance Raman spectra of filamentous bacteriophages, Raman bands of the ssDNA genome are relatively weak in comparison to those of the capsid protein, owing to the low DNA content of the virion. Further, the ssDNA bands are extensively overlapped by those of the protein, especially in the 1200–1700 cm^{-1} region. The intensities of the DNA Raman bands can be selectively enhanced through the UVRR mechanism by use of 257-nm laser excitation. This approach, which has been pursued for filamentous bacteriophages fd, Pf1, Pf3, and PH75, (Overman *et al.*, 2005; Wen, Overman and Thomas, 1997; Wen, Armstrong and Thomas, 1999; Wen *et al.*, 2001) provides an effective means of deciphering spectral contributions and structural properties of the packaged ssDNA. The Raman wavenumbers and intensities (hypochromicities) of UVRR bands of the bases in the 1200–1700 cm^{-1} interval are uniquely informative of the base environments and their interactions within the viral capsid (Wen and Thomas, 1998).

The following procedure has been employed to evaluate and interpret UVRR hypochromicities of selected base vibrations of the packaged ssDNAs of filamentous phages. The scattering cross-section (σ_n) of a Raman band of wavenumber ν_n is obtained by comparison of its peak height (I_n) with the peak height (I_s) of an internal standard (ν_s) of known scattering cross-section (σ_s) by use of Eq. (2):

$$\sigma_n = \sigma_s(I_n/I_s)(C_s/C_n) \times [(\nu_0 - \nu_s)/(\nu_0 - \nu_n)]^4 \qquad (2)$$

where C_s and C_n are the molar concentrations of the internal standard and target species, respectively, and ν_0 is the wavenumber of the exciting line, expressed in cm^{-1} (The prominent UVRR band of sodium sulfate at 981 cm^{-1}, for which $\sigma_s = 0.16$ mb at 257 nm, is employed as the internal standard (Fodor *et al.*, 1989).). In applying Eq. (2) to a deoxynucleoside constituent of ssDNA, C_n is replaced by C_b ($\equiv X_b C_n$, where X_b is the base mole fraction). The fractional hypochromicity of an ssDNA Raman band at wavenumber ν_n is defined as $1 - \gamma_n$, where the hypochromic ratio, γ_n, is the quotient of intensities in Raman spectra of the nucleic acid and constituent deoxynucleosides. In terms of the corresponding Raman scattering cross-sections,

$$\gamma_n^{\mathrm{DNA}} \equiv I_n^{\mathrm{DNA}} / I_n^{\mathrm{nuc}} = \sigma_n^{\mathrm{DNA}} / \sigma_n^{\mathrm{nuc}} \quad (3)$$

where σ_n^{DNA} and σ_n^{nuc} are Raman scattering cross-sections for the band in DNA and in a solution of the free deoxynucleosides, respectively.

The calculated UVRR cross-sections and measured hypochromic ratios for selected UVRR bands of the packaged ssDNAs of fd, Pf1, Pf3, and PH75 and comparison with dsDNA are given in Table 13.4. Representative data (for Pf3) are shown in Figure 13.11. These results are based on the assumption that for each DNA a mixture of its free deoxynucleosides would be the equivalent of a completely unstacked arrangement of the bases ($\gamma_n = 1$). In brief, the results show that the bases of Pf1 exhibit very large hypochromic ratios, indicating minimal stacking of the bases in the packaged Pf1 genome. The bases of Pf3 exhibit slightly more stacking than those of Pf1. In contrast, the hypochromicities observed for the packaged ssDNAs of fd and PH75 indicate that these genomes have very highly stacked arrangements of the bases. Surprisingly, the hypochromic effects for fd and PH75 exceed that of dsDNA, implying even closer base stacking than in *B* DNA.

13.7.3.2 **Structural Details of the Capsid Subunits**

Knowledge of the fd viral capsid symmetry and Raman tensors for appropriate vibrational modes of the pVIII subunits, many of which have been independently determined from polarized Raman studies of model compounds of known structure, permit assessment of subunit orientations with respect to the filament axis. For example, knowledge of the amide I Raman tensor (Tsuboi, Ikeda and Ueda, 1991) enables the polarized Raman spectrum of phage fd to be interpreted in terms of the angle of orientation of the subunit α-helix axis with respect to the virion axis ($16 \pm 4^\circ$) (Overman, Tsuboi and Thomas, 1996). Similar protocols were applied to the polarized Raman spectra of the class II bacteriophages Pf1, Pf3, and PH75 (Tsuboi *et al.*, 2000, 2003b, 2003a, 2005). Similarly, polarized Raman methods can be exploited to determine orientations of key tryptophan and tyrosine side chains in the subunits of both class I and class II filamentous viruses (Tsuboi, Overman and Thomas, 1996a; Tsuboi *et al.*, 1996b, 2001, 2003b, 2005). Representative polarized Raman data are shown in Figure 13.12. Details of the experimental protocols and data interpretation have been reviewed elsewhere (Tsuboi and Thomas, 2007b).

Analysis of the polarized Raman amide I and amide III signatures of the filamentous virus PH75 reveals that

The UVRR bands (left column) are in cm^{-1} units. Raman cross-sections for residues of the packaged viral ssDNA (σ^{DNA}) and corresponding free nucleoside (σ^{nuc}) are given in units of mbarn and hypochromic ratios are as defined in Eq. (3) of the text (Overman *et al.*, 2004; Wen, Overman, and Thomas, 1997; Wen, Armstrong, and Thomas, 1999; Wen *et al.*, 2001).

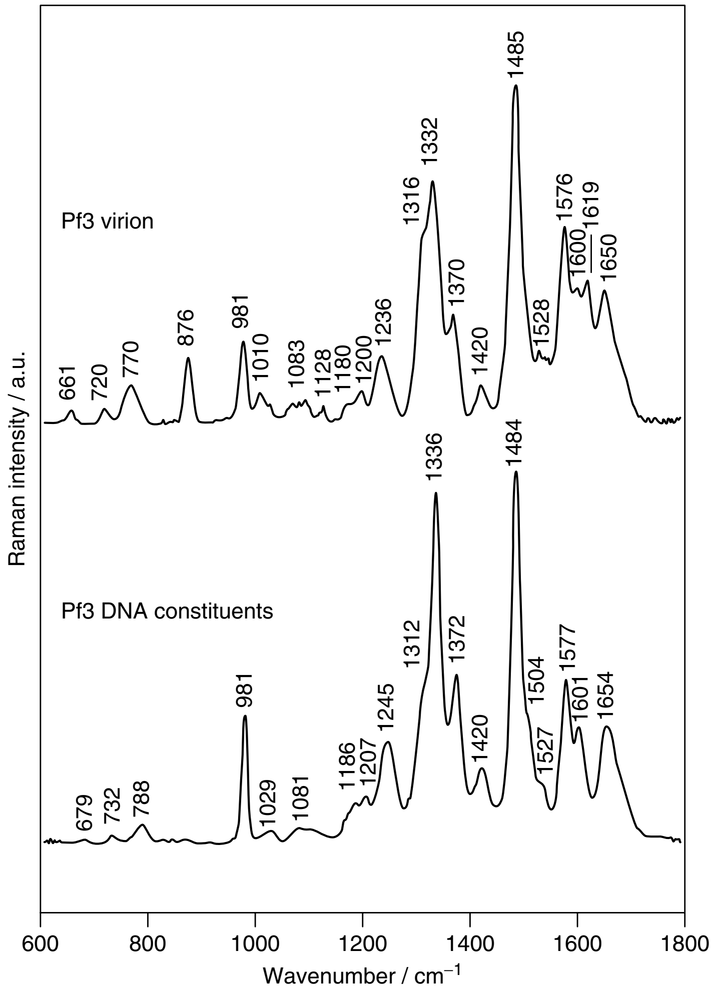

Fig. 13.11 UVRR spectra (600–1800 cm^{-1}, 257 nm excitation) of Pf3 (top) and a deoxynucleoside mixture having the same base composition (20% dA, 35% dT, 24% dG, 21% dC) as Pf3 DNA (bottom). Concentrations of the solutions of Pf3 and deoxynucleoside mixture in terms of moles of DNA phosphate are 1.04 and 0.80 mM, respectively. The concentrations of the Na_2SO_4 internal standard in these solutions are 91 and 200 mM, respectively (Wen *et al.*, 2001).

while the capsid subunit is predominantly α-helical (87%), it also contains a significant number of residues (6 ± 1 or 13 ± 3 %) differing from the canonical α-helix. This minor structural component is not apparent in the capsid subunits of the other filamentous phages (fd, Pf1, and Pf3) examined by polarized Raman spectroscopy. The Raman spectrum of PH75 also manifests local environments

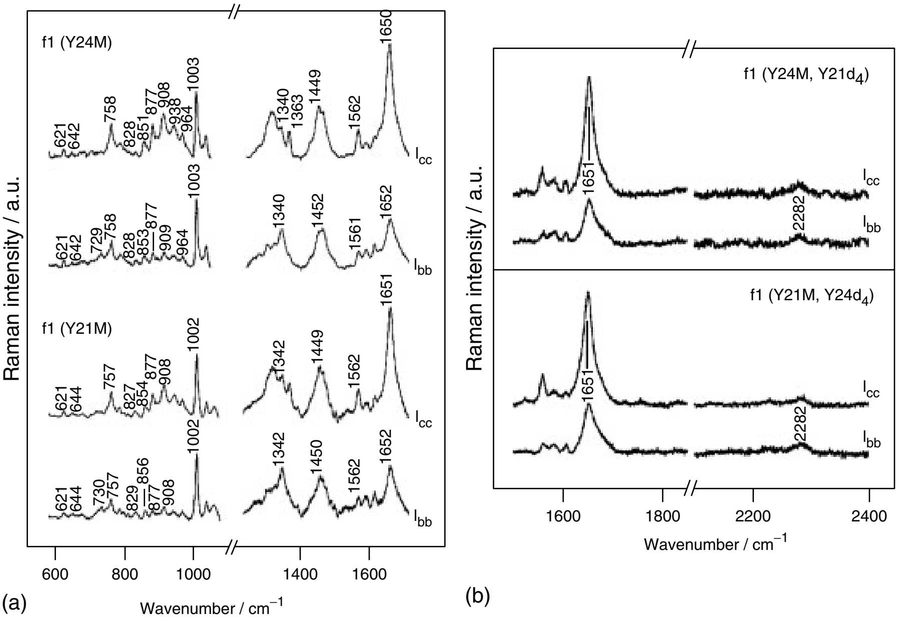

Fig. 13.12 (a) Polarized Raman spectra (I_{cc} and I_{bb}) in the spectral regions 600–1100 and 1200–1700 cm^{-1} of oriented fibers of two variants of the Ff virus (strain fl), incorporating the single-site mutations Tyr 24 → Met [fl (Y24M), top two traces] and Tyr 21 → Met [fl (Y21M), bottom two traces] in their respective capsid subunits. Raman intensities are normalized to the intensity of the isotropic marker band at 1002 cm^{-1} (Phe). (b) Polarized Raman spectra (I_{cc} and I_{bb}) in the spectral regions 1600–1800 and 2200–2400 cm^{-1} of oriented fibers of the same Ff variants in (a), which additionally carry tetradeuterio isotopomers of Tyr 21 [fl (Y24M,Y21d$_4$)] and Tyr 24 [fl (Y21M,Y24d$_4$)]in their respective capsid subunits. Accordingly, the Raman bands in the C–D stretching region are markers of the individual tyrosines (Tsuboi, 2001).

for alanine, tryptophan, and tyrosine side chains that are distinct from those observed for fd, Pf1, or Pf3. These structural anomalies were proposed to contribute to the high thermostability of the PH75 virion (Tsuboi *et al.*, 2005). Interestingly, the polarized Raman spectra of PH75 also reveal that the average peptide group of the PH75 capsid subunit is oriented with greater angular displacement from the virion axis (25°) than peptide groups of fd, Pf1, or Pf3 subunits (16°), which the indolyl ring of Trp 37 in the PH75 capsid subunit projects nearly equatorially from the α-helix axis in contrast to the more axial orientations that occur for Trp 26 of fd and Trp 38 of Pf3, and that the phenolic rings of Tyr 15 and Tyr 39 of PH75 project along the subunit α-helix axis such that one phenoxyl engages in hydrogen-bonding interaction that has no counterpart in the tyrosines of either fd or Pf1.

Analysis of the contributions of subunit tyrosine side chains (Tyr 21 and Tyr 24) to the polarized Raman spectrum of fd provides a good example of the value of the method for structural investigations of viruses. Here, single-site mutations of Tyr 21 and Tyr 24 (to methionine, Met) in the capsid subunits of fd were exploited to determine independently the orientation of each tyrosine. The mutants were also subjected to deuterium isotope-editing of the nonmutated tyrosyl ring (Overman and Thomas, 1995) in order to introduce novel tyrosyl Raman markers (C−D stretching bands in the 2200–2400 cm^{-1} region) amenable to polarized Raman analysis. The required Raman tensors for the C−D stretching bands were determined by analysis of the polarized Raman spectra obtained from an oriented single crystal of the model compound L-tyrosine-2,3,4,5-d_4 (Tsuboi *et al.*, 1998). The rationale for use of the C−D modes is based upon the fact that the corresponding Raman bands occur in a spectral region free of interference from any other Raman bands; also, the highly localized nature of the C−D stretching vibrations is considered favorable to transferability of the Raman tensors from the tyrosyl model compound to the viral subunit tyrosines. The procedure, results, and interpretation are summarized in Figure 13.13, which illustrates the coordinate systems defined for the virion and local tyrosyl Raman tensors [panel (a)], the nature of the experimental data [panel (b)], and the molecular model derived for two neighboring capsid subunits from the polarized Raman analysis (Tsuboi *et al.*, 2001) and complementary structural studies [panel (c)] (Marvin *et al.*, 1994; Overman and Thomas, 1995; Overman, Tsuboi and Thomas, 1996; Symmons *et al.*, 1995)].

13.8
Concluding Summary

Raman, UV-resonance Raman and polarized Raman spectroscopy are valuable methods for investigating structures of viral proteins and nucleic acids. The methods are also well suited to probe

Fig. 13.13 (a) The drawing at the left shows the coordinate system for the uniaxially oriented fd fiber (*abc* coordinate system) in relation to the α-helical subunit and a tyrosine side chain for which a representative Raman tensor coordinate system (*xyz*) is indicated. The drawing (not to scale) represents a small segment of the ~880 nm fd virion and a few α-helical turns of one subunit of the capsid. The drawing at the right indicates the Eulerian angles θ and χ, which define the orientation of the *xyz* coordinate system with respect to the *abc* system. Here, θ is the tilt angle (c−O−z) between the Raman tensor principal axis z and the fiber axis c, while χ is the angle (y−O−N) formed by the Raman tensor principal axis y and the line of intersection between the plane (*ab*) normal to the fiber axis and the plane (*xy*) of the phenolic ring of tyrosine. (b) Polarized Raman spectra (I_{cc}, I_{bb}) in the region 1500–2400 cm^{-1} of oriented fibers of the deuterium-labeled mutant fd viruses [designated here as f1 (Y21M;Y24d_4) and f1 (Y24M;Y21d_4) to represent virions in which, respectively, Tyr 21 is mutated to Met while Tyr 24 contains the deuterium labeling, and Tyr 24 is mutated to Met while Tyr 21 contains the deuterium labeling]. (c) Stereo diagram of the energy-minimized structure of neighboring subunits in the assembly model proposed for fd on the basis of the atomic coordinates developed for Tyr 21 and Tyr 24 from the polarized Raman spectra of panel (b) and coordinates for other residues as previously described (Marvin *et al.*, 1994; Overman, Tsuboi, and Thomas, 1996; Symmons *et al.*, 1995; Tsuboi, 1996a, 2001). The virion axis runs vertically and the subunit *N*-termini are at the top. The subunits shown correspond to index numbers $k = 0$ and $k = 5$, as defined in the Protein Databank Accession Code (Entry) 1IFJ. The molecular graphics were obtained using MOLSCRIPT (Kraulis, 1991).

the assembly pathways and architectures of native viruses. The sensitivity and selectivity shared by these spectroscopic approaches are well exemplified by the applications reviewed here to icosahedral and filamentous viruses and their constituent molecules. Significant developments in Raman instrumentation and data processing, coupled with the diversity of available sample-handling procedures and molecular biological techniques, have vastly improved the scope of Raman methods for studies not only of viruses but also of other biological macromolecular assemblies.

In the applications considered above, it must be stressed that accurate Raman vibrational band assignments are

essential. Only with reliable assignments can the Raman spectrum be effectively exploited to investigate molecular structural details, including sites of intermolecular recognition and local and global changes in structure attendant with biomolecular recognition events. We have shown how the use of isotope-editing procedures and recombinantly engineered mutational substitutions can be used to advance Raman vibrational assignments that lead to definitive interpretations of the spectroscopic data. Statistical treatment of the spectra is also shown to facilitate quantitative analysis of physicochemical properties and provide improved understanding of the biological significance of the results.

14.1
Introduction

X-ray scattering measures instantaneous spatial correlations of electron density and more recently through the development of inelastic X-ray scattering, space–time correlations of electron density. By various modes of applications, it can provide structural as well as dynamical information. Compared with many other experimental tools that have been applied to lipid assemblies, X-ray has a clear advantage on structure determination, as evidenced by its definitive proof for the lipid bilayer structure in cell membranes. This article describes X-ray methods for structural determination of lipid assemblies and emphasizes applications to biophysical studies. So far X-ray methods have seldom been applied to native biological membranes. This is because for biophysical applications the purpose is to find the cause–effect relationships underlying biological phenomena. Diffraction or scattering from cell membranes that typically contain thousands of different lipid components and thousands of different proteins can never have an unambiguous interpretation. Thus the methods we describe here apply to artificial membranes composed of selected lipid components to which selected membrane-active molecules, such as proteins or drugs, are added.

14.1.1
Basic Structure of Lipid Bilayers

Until the early 1970s, the hypothesis that the basic structural element of biological membranes is a bimolecular layer of phospholipid molecules was seriously doubted due to the lack of direct evidence. The direct evidence was finally provided by X-ray diffraction of membranes and lipid bilayers (Levine and Wilkins, 1971; Wilkins *et al.*, 1971). Diffraction from dispersions of *Mycoplasma laidlawii*, erythrocyte, and other membranes showed the same basic features of diffraction from phospholipid bilayers, proving that a phospholipid bilayer is the major structural component of native membranes. These classic experiments established the salient features of diffraction from lipid bilayers, both from dispersions of bilayer vesicles and from oriented stacks of bilayers.

Diffraction from oriented stacks of lipid bilayers consists of low-angle lamellar reflections and a paraffin-like 0.46-nm diffuse band oriented at right angles to the lamellar diffraction. The

ISBN: 978-3-527-40702-6

complete absence of any other low-angle diffraction indicates that the lipid chains are uniformly packed in the bilayers. This is contrary to many polymers that give strong low-angle diffraction due to irregularities in their chain packing. The 0.46-nm diffraction band is informative about the configuration and packing of the lipid chains. For fully saturated chains, the band shifts to a sharp 0.415-nm peak at low temperatures corresponding to the hexagonal packing of extended (all-*trans*) *n*-alkanes. The distance between two parallel, partially disordered chains is roughly 0.46 nm, as in liquid paraffins. The angular variation of the radially integrated intensity of the band provides a measure for the orientation of the chains in a bilayer. The radially integrated intensity is maximum at the equator and generally drops to less than 20% of the maximum within 40° as the angle increases toward the meridian. Conceptually one may picture the hydrocarbon region of the bilayer as an assembly of domains of locally correlated chain segments. The direction of chain segment varies continuously throughout the medium, but within a small domain the chain segments are nearly parallel. The domains diffract independently in a plane perpendicular to the axes of the chains. Thus the majority of the domains have the chain orientations more or less perpendicular to the plane of the bilayer. Such chain configurations put the terminal methyl groups near the middle of the bilayer and the glycerol ends of the chains to the surface of the hydrocarbon layer. This basic structure of lipid bilayers was reconfirmed by the electron density profiles constructed from the low-angle lamellar diffraction.

In many biophysical applications, the goal is to measure the structural changes of the host lipid bilayer caused by the addition of membrane-active components, or determine the distribution of the added components in the host bilayer. Therefore, it is important to remember the basic feature of the diffraction pattern from a lipid bilayer as described above. The simplest application is the measurement of the changes of the electron density profiles across the bilayer. This is very useful for studying the interaction of membrane-active molecules with membranes. We will illustrate three different examples: location of ion-binding sites, hydrophobic matching, and membrane thinning by antimicrobial peptides. The distribution of added molecules in a lipid bilayer can be measured by in-plane scattering, making use of the clean background outside of the lamellar diffraction and the diffuse band due to the chains. We will illustrate the method of in-plane scattering with gramicidin channels embedded in two different lipid bilayers.

14.1.2
Nonlamellar Structures of Lipid Assemblies

Besides bilayers, lipids and water have the potential to form wide varieties of nonlamellar assemblies, such as micellar, hexagonal, and cubic phases (Luzzati, 1968; Luzzati *et al.*, 1968; Tardieu *et al.*, 1973). It has long been recognized that many functions of membranes, particularly their abilities of shape changes (such as fusion, fission, and pore formation) are related to the intrinsic properties of lipid components that are capable of forming nonlamellar phases (Luzzati, 1968; Gruner, 1989). It has also been speculated that the lipid components that have the tendency of forming nonlamellar phases might create stresses in the lipid bilayer and consequently play a role of regulating the functions of membrane proteins (Gruner, 1989).

The majority of known lipid–water phases were discovered and studied by Luzzati and collaborators in the 1960s (Luzzati, 1968; Luzzati *et al.*, 1968; Tardieu *et al.*, 1973) (the earlier work referenced in Luzzati, 1968), but discoveries of new phases still continue as investigators broadened the range of chemical variables. New phases, even within lamellar phases (e.g. Yang and Fukuto, 2005), will undoubtedly continue to be discovered as the number of lipid components increases and greater varieties of lipid are investigated. There is no doubt in our mind that the field of structures of lipid assemblies is still in its infancy and will continue to grow as its impact on biology and technology increases.

As pointed out by Luzzati (1968) and Tardieu *et al.* (1973), one of the most remarkable characteristics of lipid–water mixtures is their ability to combine in one phase a periodically ordered long-range organization in one, two or three dimensions and a highly disordered short-range conformation in the unit cells. It is this unique property that makes the structural problems of lipid assemblies amenable to X-ray analysis. As in protein crystallography, the phase problem is the main obstacle for the reconstruction of electron density. But for two basic reasons, the well-developed phasing methods for protein crystallography are in most cases not applicable to lipidic structures. First, due to the short-range disorder a lipidic structure is described by an electron density distribution, not by atomic positions. Secondly, while most proteins are not centrosymmetric, most lipid assemblies prepared from lipid/protein/water mixtures are. The phasing methods of protein crystallography are based on atomicity (the electron density is zero between atoms) and are often specifically for noncentrosymmetric structures (Grossmann and Arnold, 2001). Thus a routine technique for phasing the diffraction amplitudes from lipid assemblies is yet to be developed, except for the simple case of lamellar phases. The phase problem for lamellar phases has been routinely solved by the swelling method (Perutz, 1954; Blaurock, 1971). But the phase problem for every nonlamellar assembly is a challenge.

In this article we describe methods and applications by examples. Besides applications in lamellar systems, we show successful solutions to structural problems in several nonlamellar phases, including inverted hexagonal phase, distorted hexagonal phase, and rhombohedral phase. Missing from the list are the structural problems of cubic phases. Since Scriven (1976) suggested that the bicontinuous cubic phases are based on the infinite periodic minimal surfaces, there have been a great deal of theoretical and experimental interests on these structures (Longley and McIntosh, 1983; Mariani *et al.*, 1988; Luzzati *et al.*, 1992; Seddon and Templer, 1993; Harper and Gruner, 2000; Harper *et al.*, 2000). Cubic phases are different from all other lipid–water phases in having a large water spacing (swollen), hence free of bilayer–bilayer interactions. It is considered the ideal system to study the curvature and the chain-packing energies. Structural problems of cubic phases are on-going research projects (Harper and Gruner, 2000; Harper *et al.*, 2000; Conn *et al.*, 2007). It is premature to be included in encyclopedia.

As for the fundamental theory of X-ray diffraction, we recommend the book by Warren (1969). Since lipid–water systems diffract easily even for poorly prepared samples, it is worth pointing out that a rigorous analysis of diffraction data is possible only for well-defined samples with a well-defined diffraction geometry (Warren, 1969). For this reason, we start with sample preparation and the diffraction technique for each type of sample.

14.2
Sample Preparation and Instrumentation

In this chapter, we discuss the types of samples that are used to study molecular assemblies of lipids and the X-ray scattering method suitable for measuring them. We will only focus on elastic scattering (including diffraction), in which the scattered X-rays have the same energy as the incident X-ray. Inelastic scattering (e.g. Chen *et al.*, 2001) and X-ray spectroscopy (e.g. Biou *et al.*, 2005) of lipid assemblies are possible but will not be discussed here, since their applications are still very limited. Coherent X-ray scattering may also be useful for studying the dynamics of lipid assemblies. However, to date its application to membrane structures remains a fascinating possibility rather than a reality.

An elastic X-ray scattering measurement is equivalent to taking the Fourier transform of the electron density distribution in the sample. The recording on the detector is in the reciprocal space. The structures at different length scales in the sample manifest as diffraction or scattering features at different q values in the reciprocal space. Here $q = 4\pi \sin\theta/\lambda$ is the scattering vector, or the momentum transfer of the scattering, with 2θ being the scattering angle between the incident and scattered rays and λ the X-ray wavelength. The magnitude of q is inversely proportional to the length scale probed by the X-rays. Sharp diffraction peaks are characteristic of periodically ordered structures. Bragg's law correlates the peak position in the reciprocal space to the spacing of the periodic order, while the direction of q is the orientation of the periodicity. Structures without long-ranged order (e.g. liquid-like in-plane structures, fluctuation of membranes) do not produce Bragg peaks, so their analyses are more complex. However, the reciprocal relationship between q and real space spacing still holds true. A diffused peak often signifies a characteristic length or an average spacing.

Oriented stacks of lipid bilayers produce three diffraction or scattering features, schematically shown in Figure 14.1. The most prominent are the Bragg peaks associated with the periodic layers, with the first order typically at $q_z \sim 1\ \text{nm}^{-1}$ (lamellar spacing $D \sim 6$ nm). The second feature is due to the chain–chain correlations in the bilayers, which manifest as a broad peak at $q_r \sim 14\ \text{nm}^{-1} (q_r = \sqrt{{q_x}^2 + {q_y}^2})$, corresponding to $\sim$0.45 nm spacing between parallel chains. Finally, if there are supramolecular structures (e.g. membrane pores or protein assemblies) within the membrane, additional scattering peaks may appear. It is important to remind ourselves that all scattering features from a system are related. Therefore, a good experimental procedure should record the complete scattering pattern first, even if the purpose is to analyze only one of the many features,for example the lamellar diffraction.

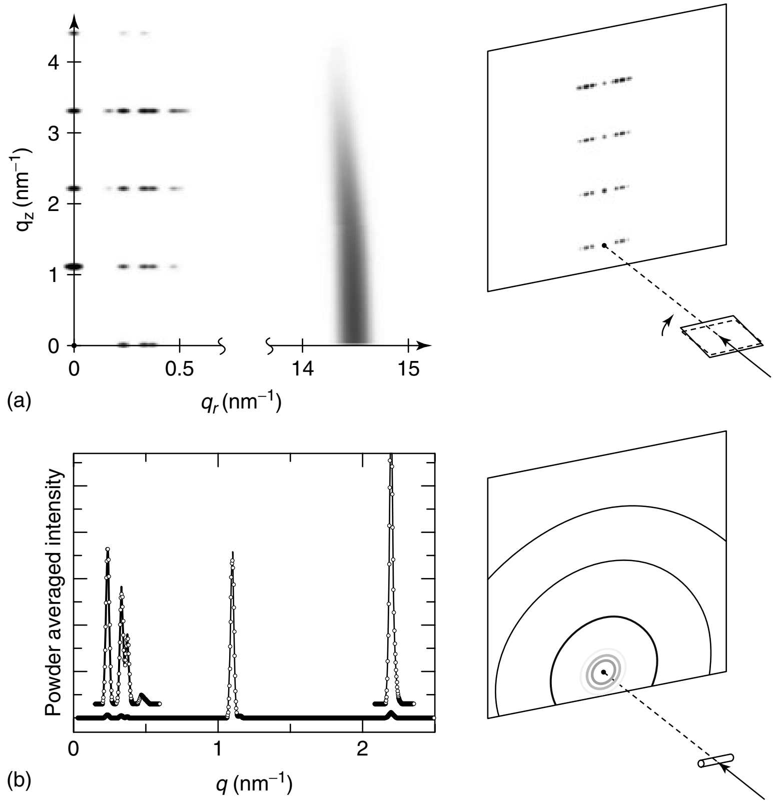

Fig. 14.1 (a) Simulated diffraction pattern on the $q_z - q_r$ coordinates from oriented stacks of bilayers in the square phase (Yang and Fukuto, 2005). The pattern includes lamellar peaks on q_z, a paraffin-like broad band, and satellite peaks next to the lamellar peaks. The last feature represents a supramolecular ordering within the bilayers. All three features are seen clearly in this diffraction geometry. (b) The same diffraction pattern measured by powder diffraction.

14.2.1
Sample Preparation

14.2.1.1 **Powder Sample**

Powder samples that contain randomly oriented structures are fairly easy to prepare and measure. These samples can be prepared by simply mixing lipids with water. Repeated freeze–thaw cycles are used to improve sample homogeneity. The sample is often housed in a thin-walled capillary tube and measured in transmission geometry.

Since the structures within a powder sample are randomly oriented, the scattering pattern contains only rings concentric to the direct beam, as shown in Figure 14.1b. Scattering data can be recorded using either an area detector or a linear detector. In order to ensure good powder averaging, the capillary tube is often rotated during measurements.

Powder samples are convenient if the purpose is to determine the lattice constant or to determine the lattice symmetry, but not ideal for the studies of structures. Diffraction peaks that are clearly resolved in the $q_z - q_r$ plane (Figure 14.1a) may have a similar magnitude of $|q|$ and therefore not distinguishable in powder diffraction. This is especially problematic for lipid assemblies because their diffraction peaks are not sharp due to their soft nature. The situation is worse if the lattice constant is large. For example, the unit cell in the square phase (Yang and Fukuto, 2005; Figure 14.1a) is ~10 times the layer spacing. In such cases even the identification of the lattice symmetry becomes difficult by power diffraction.

14.2.1.2 **Oriented Lipid Multilayers**

To record the complete diffraction pattern of membranes one must use oriented multilayers. All examples presented in the following chapters are based on this type of samples. The most important advantage of aligned samples is the separation of the q_r and q_z components of the scattering vector. The three diffraction features of membranes are clearly separated (Figure 14.1a). And the identification of lattice symmetry is greatly simplified.

There are several methods for preparing aligned lipid multilayers (Huang and Olah, 1987; Ludtke *et al.*, 1995). The most commonly used method is solvent casting. Lipids and other components, such as membrane-active proteins, are first codissolved in organic solvents. The solution is directly deposited on a clean, flat substrate (glass or silicon). Lipid multilayers (even nonlamellar phases have layered structures) form spontaneously as the solvents evaporate and the lipids hydrate from water vapor. The choice of the solvent is crucial for forming a uniform film (Ludtke *et al.*, 1995). The primary requirement is that the solvent system must have an appropriate surface tension and evaporation rate for the size of the substrate being used. For example, pure chloroform causes more sample to aggregate at the center of the substrate and tends to leave "rings" behind as it evaporates. Pure trifluoroethanol, on the other hand, causes a very smooth deposition in the center of the substrate, but most of the material aggregates along the edges of the substrate. Of course, chloroform evaporates much more rapidly than TFE, and what really matters is the surface tension near the end of the evaporation process. A mixture of three parts chloroform and one part TFE produces good results for most pure lipids. The mixing ratio may need to be adjusted depending on the materials used and other solvent may be added to improve the solubility of nonlipid components. Trial and error is required when working with a new lipid–protein system, but once the method has been refined, new samples can be made quite rapidly and reproducibly.

Thick aligned multilayers can be prepared by (i) lyophilizing the lipid–protein mixture, (ii) hydrating the mixture by saturated water vapor, and (iii) sandwiching the mixture between two flat plates (Huang and Olah, 1987). Although beryllium has been used for this purpose, for safety reason, thin silicon plates might be a better choice. Thin silicon plates are also partially transparent to long wavelength visible light (red) as silicon transmission starts to rise toward IR spectrum. Optical observation of the sample (for the inspection of smectic defects in the sample (Huang and Olah, 1987; He *et al.*, 1996)) is therefore possible.

Freestanding films are another form of aligned multilayers that have been widely used in liquid crystal research community. They are prepared by spreading a powder sample across an aperture. Although successful experiment has been carried out with freestanding films (e.g. Smith *et al.*, 1988) and in some cases even the number of bilayer in the film can be precisely controlled (Chiang *et al.*, 1995), in general these samples are not easy to prepare and the film tends to rupture when the lipid undergoes a phase transition.

14.2.1.3 **Other Sample Configurations**

Lipid vesicles are attractive membrane samples because they resemble the morphology of cell membranes. Vesicle samples can be prepared by extrusion or sonification of a lipid suspension (e.g. Brzustowicz and Brunger, 2005). The advantage of vesicles is that not only additional molecules could be incorporated into the lipid bilayer, but the chemical environment of the membrane could also be varied. However, the vesicle concentration must be low to avoid vesicle–vesicle correlations. Therefore, one must work with data of low intensity. Like small angle scattering, the data analysis is typically by model fitting.

Another type of lipid membrane sample that has been widely studied is the lipid monolayer, which can be prepared by spreading a lipid solution in organic solvent onto the surface of water. A Langmuir trough provides the means of controlling lipid area density or the surface pressure of the monolayer by moving a barrier that changes the surface area of the monolayer. Owing to the very small sample volume, X-ray scattering from a monolayer is weak. The measurements are often conducted with the X-ray incident angle below the critical angle so as to take advantage of surface-enhancement of scattering intensity. For small incident angles, this can be achieved by using a deflecting mirror. More flexible scattering geometry requires a dedicated liquid diffractometer. From the scientific point of view, monolayers may not be good representatives of biological membranes for the obvious reason that the latter are bilayers. There are examples that have shown that transmembrane proteins (e.g. gramicidin) in monolayers behave very differently from those in bilayers.

Recently, X-ray scattering measurements from a single bilayer freely floating between two boundaries (Daillant *et al.*, 2005) or supported on a solid substrate have been reported (Miller *et al.*, 2005). The presence of the surrounding bulk water necessitates the use of relatively high-energy X-rays (e.g. 1 cm of water transmits ~28% of 16 keV photons but only 0.004% of 8 keV photons). In either case, the diffraction geometry was restricted by the sample arrangement and the scattering from a single membrane was weak. We expect further progress from these methods.

14.2.2
Instrumentation

Figure 14.2 illustrates the typical experimental setup for measuring X-ray scattering from lipid samples. The X-rays generated by a source are trimmed by multiple sets of collimators (slits or apertures). Focusing optics (mirror or bent multilayer) are often utilized to increase the flux of X-rays that pass through the collimators or to improve the angular resolution. The sample is usually kept

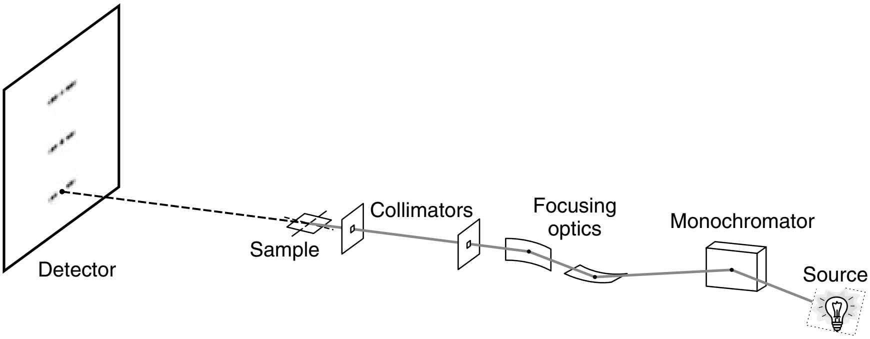

Fig. 14.2 Typical experimental setup for X-ray scattering measurements of lipid assemblies. A side-bounce monochromator, an oriented sample and an area detector are shown. The components can be implemented in many different ways.

in an enclosure in which the sample environment (temperature and humidity) is under experimental control. The sample chamber is mounted on a manipulator that can translate and re-orient the sample with respect to the X-ray beam. The detector at the opposite end collects the scattering data. Whenever possible, helium-filled or evacuated beam paths are used to reduce air absorption and scattering.

Most measurements on powder or aligned multilayer samples can be carried out using a sealed tube X-ray generator. This is especially true as more and more lab-based diffractometers are now equipped with focusing optics. However, for measurements that require extremely high angular resolution, very short data collection time or energy tunability (e.g. anomalous diffraction), synchrotron-based instruments are necessary.

One important aspect of the X-ray experiment is the manipulation of the sample's position and orientation during the measurement. For example, the powder sample of a lamellar phase is a collection of multilayered vesicles, which are usually not an ideal powder (giving nonuniform powder rings). The powder averaging can be improved by rotating the sample during the measurement. An aligned sample needs to be oriented correctly with respect to the incident X-ray and then rotated during the measurement to give the complete scattering pattern. The diffraction geometry must be well defined relative to the sample position for the scattering intensity to be correctly normalized between data points.

Not often appreciated is the fact that aligned multilayers are two-dimensional powder samples. Its powder nature (orientational randomness) is impossible to control during the sample preparation. In fact, a well-aligned sample may have larger domain sizes that tend to make the powder averaging less complete. An example is given in Figure 14.3, which lacks the left–right symmetry in intensity due to the incomplete powder averaging. An in-plane rotation of the sample during the measurement can alleviate this problem. An alternative is to translate the sample to increase the averaging sample volume. Sample translation has the added benefit of reducing the radiation dose that would decrease the possibility of radiation damage. Indeed,

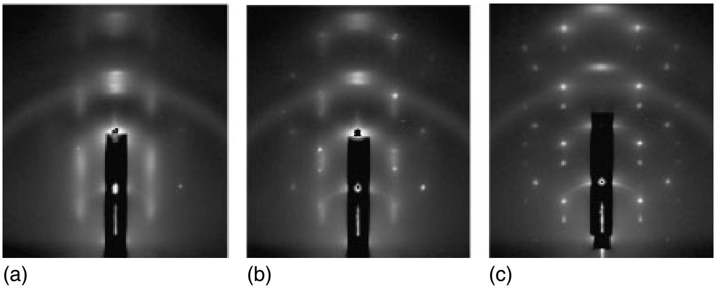

Fig. 14.3 An example of imperfect powder averaging. Aligned multilayers of a peptide–lipid mixture (magainin in 3 : 1 DMPC/PG) measured at 25 °C. (a) At 98% RH magainin formed pores in fluid bilayers. The satellite diffuse bands are due to the interference between the diffusing pores as in a 2D liquid. (b) and (c) at 96% RH and 93% RH, respectively, the pores were correlated to form a periodic lattice. The pattern in (b) shows left–right asymmetry indicating imperfect in-plane powder averaging.

radiation damage is of great concern for diffraction experiment of lipid assemblies, particularly when synchrotron radiation is used. Careful experimenters examine the samples by thin layer chromatography (Skipski *et al.*, 1962) after the measurement.

Another aspect of sample manipulation is the control of the environment surrounding the sample. The lipid structure can be very sensitive to the temperature and the water content of the sample (Figure 14.3). Accurate control of the sample temperature is usually not a problem using commercial devices. For powder samples, the water content can be adjusted by using the gravimetric method (by weight) or by mixing the sample with a polyethylene glycol (PEG) solution of known osmolality. For aligned multilayers, the water content in the sample is controlled by the ambient humidity. Unfortunately, good humidity controls are not commercially available. A practical humidity control can be achieved by heating/cooling a water reservoir based on the feedback from a humidity sensor (Yang and Huang, 2003).

The detector is selected based on the consideration of the desired angular resolution and the speed of measurement. A point detector with collimators (Figure 14.4a) that limit the direction of X-rays entering the detector usually gives the best angular resolution. The collimators also keep background scattering minimal by allowing only the X-rays scattered from the sample to be counted. However, the point-by-point data collection necessarily prolongs the sample exposure to X-rays. A linear detector collects scattering data simultaneously in a linear array of pixels. High angular resolution is achievable in the direction perpendicular to the pixel array by utilizing Soller slits (Figure 14.4b).

For the sake of speed, an area detector is much preferred. However, one must be aware of its potential problems. First, the background noise could be strong and uneven because the entire path of the incident beam is the potential source for unwanted scattering. Secondly, the diffraction peak may appear to be smeared, especially at wide scattering angles. This is because the detector at

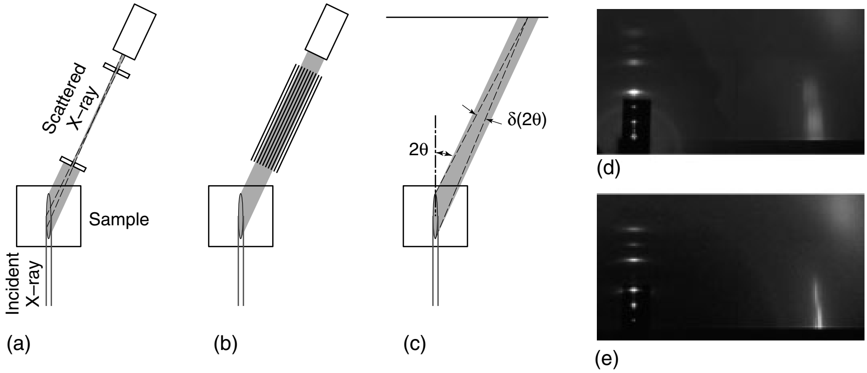

Fig. 14.4 Angular resolution (top view) in a grazing incidence reflection measurement. (a) A point detector with slit collimation gives the best resolution. (b) A linear detector with Soller slits improves the resolution in one direction. (c) An area detector may have problems with resolution, particularly at wide angles due to the long incident footprint. (d) and (e) are scattering patterns from the same sample under identical conditions, except that in (d) the full length (20 mm) of the sample was illuminated by X-rays, whereas in (e) the X-ray beam was focused to ~20 μm at the sample in the direction along sample normal and therefore resulted in a footprint of ~3 mm at 0.4° incident angle.

a wide scattering angle "sees" a large incident beam footprint (Figure 14.4c). The improvement in resolution by a focused beam (Yang, 2005) is illustrated in Figure 14.4d and e. If the available beam is not a focused beam, reducing the sample size could also help.

14.3
Structural Problems in Lamellar Phases

The peaks of lamellar diffraction are confined to the *c*-axis normal to the periodic layers (designated as the z-axis). Therefore, the constructed electron density represents the structure averaged over the $x - y$ plane and has only the z dependence. In a fluid-phase phospholipid bilayer, the only structural parameter that can be measured to a high accuracy is the phosphate-peak to phosphate-peak distance (PtP). PtP is a measure of the membrane thickness. Since a lipid bilayer is an elastic body, a change in the membrane thickness from its unperturbed value would induce an elastic stress that could act directly on an embedded protein. Thus, a protein-induced change in the PtP is a quantity that directly measures the degree of protein–lipid interaction. Two such examples will be illustrated below. In another example, we show that it is possible to find the location of heavy atoms in a fluid lipid bilayer.

Oriented stacks of lipid bilayers are preferred for lamellar diffraction. Owing to the difference in the Lorentz factor, a powder sample (that has a Lorentz factor $\sim 1/h^2$, h being the Bragg order) rarely produces more than four Bragg orders, whereas aligned multilayer samples (Lorentz factor $\sim 1/h$) typically produce 6–8 orders. Since the diffraction pattern is limited to one axis, a point detector rather than an area detector is preferred for limiting the background signal to minimum. In particular, if a diffraction beam monochromator is used, the Compton scattering and the fluorescence from the sample can be screened, and it can also be set up to bias against higher harmonics. Keeping the background to minimum allows the measurement of weak high-order peaks. The relative contribution of high-order peaks to the electron density is magnified by the Lorentz factor; therefore, small high-order peaks are not negligible. This is important if one wishes to measure the PtP as accurately as possible.

Multilayer samples are measured in a temperature–humidity chamber. In most cases one wishes to measure the membrane properties in the fluid phase of the lipid chains and as close to full hydration as possible. However, it is well known that membranes in full hydration undergo undulation fluctuations that damp the high-order diffraction peaks and broaden the remaining ones (Caille, 1972), making structural analysis difficult. It has been shown that although the lamellar spacing D tends to diverge as the hydration level reaches 100% humidity, the bilayer thickness PtP does not. Indeed, the PtP value at full hydration can be extrapolated from a series of measurement at less than full hydration levels (Chen *et al.*, 1997). For practical purpose, one can measure the bilayer thickness of full hydration approximately at the highest humidity level (~98% RH) without the damping effect of undulation fluctuations.

We illustrate the technical details of the method in the first example below.

14.3.1
Ion-Binding Sites of the Gramicidin Channel

Gramicidin is by far the most extensively studied membrane-active peptide that forms a transmembrane ion channel. A complete characterization of this channel is desirable as a case study of ion transport across a membrane. The channel selectively facilitates the diffusion of monovalent cations across the membrane, but does not transmit anions or divalent cations. Experiments have indicated that there are two monovalent binding sites in the channel, but their locations cannot be determined from the molecular structure of the channel, nor does gramicidin form crystals in the channel form. The problem then was to determine the ion-binding sites in the gramicidin channels embedded in fluid lipid bilayers.

Gramicidin channels were incorporated into dilauroyl-phosphatidylcholine (DLPC) bilayers to a peptide–lipid ratio of 1 : 10. Identical multilamellar samples were prepared with K^+, Tl^+, Ba^{++}, Mg^{++}, or without salt (Huang and Olah, 1987). The sample was kept in a temperature– humidity chamber and Bragg diffraction was measured with a point detector using the $\omega - 2\theta$ geometry.

One unique feature of membrane diffraction is that the repeat spacing is more than 30 times the X-ray wavelength. The scattering vector $\boldsymbol{q}$ satisfying the Bragg law lies very close to the surface of the Ewald sphere. As a consequence, it is very easy to obtain incorrect diffraction amplitudes with the sample misaligned in χ without realizing it (χ is the rotational angle around the line of intersection between the plane of scattering and the sample plane). A procedure for positioning and orienting lamellar samples was described in Wu *et al.*, (1995). A two-dimensional $\omega - \theta$ scan around the second or third Bragg order can be used to check the alignment of the ω-angle. A correctly aligned sample has the peak

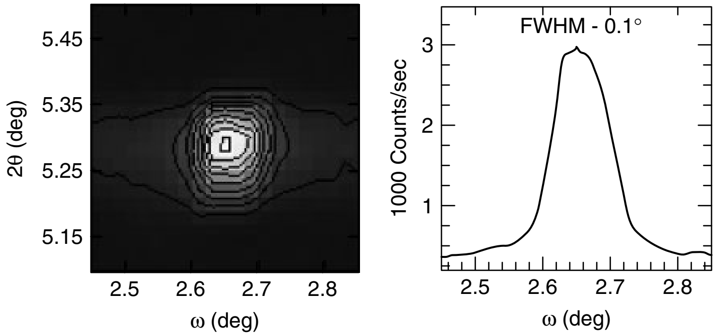

Fig. 14.5 (Left) An example of two-dimensional $\omega - \theta$ scan around the third Bragg peak of an aligned multilayer sample of peptide–lipid mixtures. The sample was well aligned and showed a single peak on a flat background. (Right) A cut through the center of the peak at constant θ corresponds to the ω rocking curve. The FWHM of the rocking curve is 0.18, the same as the limiting resolution of the apparatus. The background below the Gaussian fit to the rocking curve is negligible, implying very little powder diffraction (Weiss *et al.*, 2003).

position exactly at $2\omega = 2\theta$ in the $\omega - \theta$ plane. Also, the quality of the sample could be assessed from this scan: a well-aligned sample exhibited a single Bragg peak on a flat even background, whereas poor alignment showed up as a broad shoulder along ω. An example of well-aligned sample is shown in Figure 14.5.

The $\omega - 2\theta$ scan was recorded with a step size of $\Delta\theta = 0.01°$ (Figure 14.6). To make use of the swelling method, the scan was repeated at several humidity

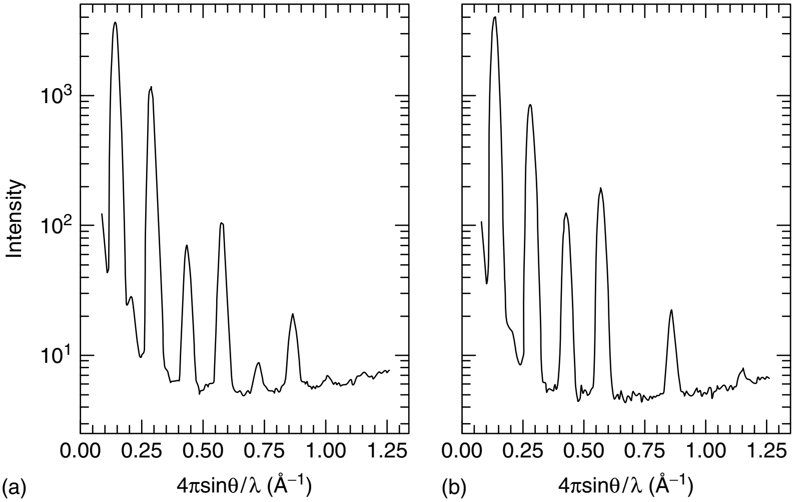

Fig. 14.6 Lamellar diffraction patterns of gramicidin–DLPC multilayers: (a) with Tl^+ ions and (b) without salt. Eight Bragg peaks were recorded. The lamellar spacings were 4.34 nm for both patterns (Olah *et al.*, 1991).

levels. Only consecutive scans that overlapped within the experimental errors indicating that the sample condition did not change during the scan were averaged and subsequently analyzed. Data reduction consisted of the following steps on the basis of the correction factors expressed as (Wu *et al.*, 1995).

$$E = I_0|F|^2 \, C_P C_L C_A C_V \qquad (1)$$

E is the measured intensity. The form factor square $|F|^2$ is the quantity we wish to obtain. I_0 is proportional to the incident intensity, and C's are the correction factors. (i) Background subtraction. This usually presents no problem except for the small high-order peaks. If that were the case, the high-angle region was scanned over a longer time until the background was smooth. (ii) Corrections for C_A, the factor of intensity decrease due to absorption, and for C_V, the diffraction volume. These corrections (particularly the first few Bragg orders) are sensitive to the beam geometry, so they are best calculated by constructing a ray diagram based on the sample and beam geometry (Wu *et al.*, 1995). The rest of the data reduction was not sensitive to the small variation of θ, so after the corrections (i) and (ii) the intensity was integrated for each Bragg peak to obtain the integrated peak intensities. (iii) The polarization factor C_P depends on the beam polarization and the diffraction geometry (Warren, 1969). For an unpolarized beam and with a diffraction beam monochromator is $C_P = (\cos^2 2\theta \cos^2 2\theta_M + 1)/2$, where θ_M is the monochromator angle. $C_P = (\cos^2 2\theta + 1)/2$ without the monochromator. (iv) The Lorentz factor $C_L = 1/\sin 2\theta$ (Warren, 1969).

We note that there is one more possible correction to be considered. If the incident X-ray beam has an angular divergence and the sample is mosaic, the vertical size of the Bragg reflections will increase with order. In the vertical direction, the slit width may be smaller than the width of the Bragg reflection; therefore, a correction factor has to be introduced that accounts for the increasing loss in intensity with order (Saxena and Schoenborn, 1977). This correction factor is usually important only for neutron diffraction.

After the corrections, we obtained the relative magnitudes of the diffraction amplitude $|F(q)| = |F(2\pi h/D)|$ for the diffraction pattern of lamellar spacing D and Bragg order h. The amplitude $F(q)$ is a real quantity since the bilayer made from a mixture is centrosymmetric. The phase problem is to determine its sign. This is usually done by the swelling method (Perutz, 1954; Blaurock, 1971) based on the idea that in most cases the structure of a lipid bilayer does not change much with hydration changes. Let us assume that the structure of the bilayer is invariant under a change of hydration level, which merely changes the thickness of the water layer. Then one can show that the diffraction amplitudes at lamellar spacing D satisfy Blaurock's scaling relation (Blaurock, 1971)

$$\sum_h \left| F\left(\frac{2\pi h}{D}\right)\right|^2 = \frac{D}{D_0} \qquad (2)$$

where D_0 is an arbitrary constant. Therefore, the diffraction amplitudes obtained from the raw data at each hydration level are first scaled to satisfy the relation (2). The scaled amplitudes are then plotted in the q space, and the phases are chosen so that a smooth curve would connect all the data points: we call this a phasing diagram. Examples are given in Figure 14.7. This is because if the bilayer is invariant, the form factor of the lipid bilayer (minus the water background) should be the same independent of the lamellar spacing. Indeed, one can construct the form factor $F(q)$ from one set of data of lamellar spacing D, called *the Shannon curve,*

$$F(q) = \sum_h F\left(\frac{2\pi h}{D}\right) \frac{\sin(qD/2 - h\pi)}{qD/2 - h\pi} \tag{3}$$

and the curve should go through the data points of all other lamellar spacings, provided the phases have been chosen correctly. As pointed out by Torbet and Wilkins (1976) and Olah *et al.* (1991), in real systems the bilayer is most likely slowly changing with the hydration. In that case the phases should still be chosen so that the data points of different D are smoothly connected as in Figure 14.7. This method apparently works for the majority of lamellar diffraction. With the phases determined, the diffraction amplitudes can be used to construct the unnormalized electron density $\rho_{\mathrm{ex}}(z)$

$$\rho_{\mathrm{ex}}(z) = \sum_h F(2\pi h/D)\cos(2\pi hz/D) \tag{4}$$

Because the diffraction intensity was not normalized (to the amount of sample) and the zeroth order was not measurable, the experimental density is related to the true density $\rho(z)$ by two unknown constant parameter a and b

$$\rho(z) = a\rho_{\mathrm{ex}}(z) + b \tag{5}$$

We need two conditions to determine a and b. For example, if the molecular composition of the bilayer is known (one might need to estimate the number of water molecules per lipid), one condition is $\int \rho(z)dz =$ number of electrons from the molecular composition. Another condition is that the density at the center of bilayer is that of the methyl group, $1.7 \times 10^2\ \mathrm{e\,nm^{-3}}$. The details of the normalization procedure for the

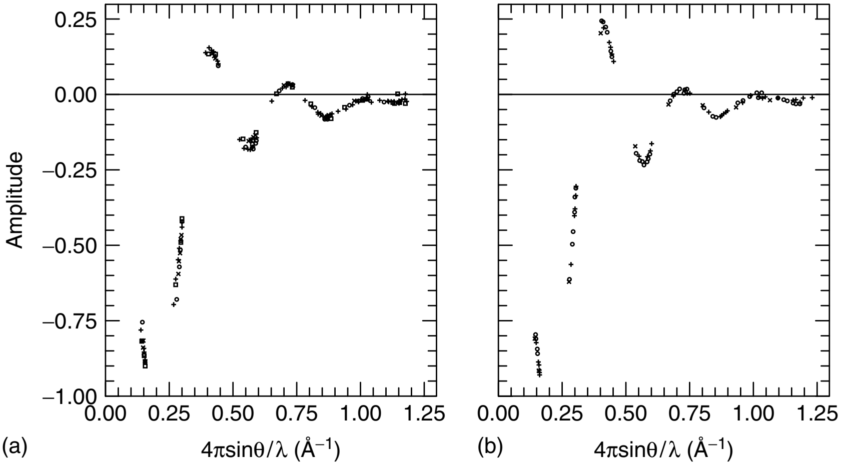

Fig. 14.7 Phasing diagrams. The signs of the diffraction amplitudes were chosen so that the data points fall on a single smooth curve. (a) the Tl^+ sample and (b) the salt-free sample were measured at several different hydration levels (Olah *et al.*, 1991).

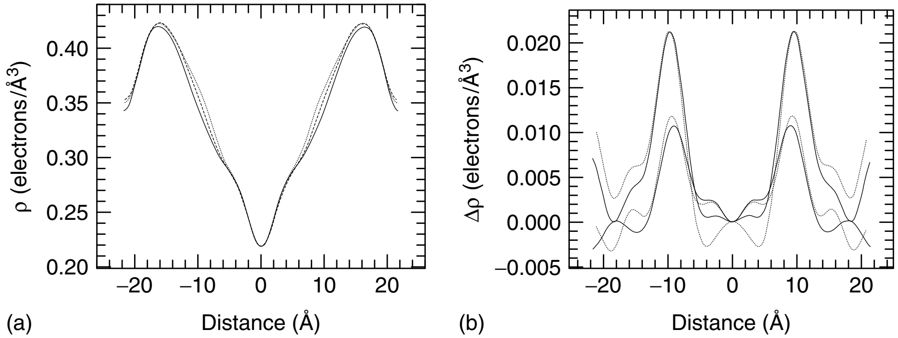

Fig. 14.8 (a) Normalized electron density profiles of gramicidin–DLPC bilayers with Tl^+ (dotted line), with K^+ (broken line), and without salt (solid line), obtained from the diffraction amplitudes at lamellar spacing 4.34 nm. (b) Difference in elelctron density profiles. The top 2 are $\rho(Tl^+)-\rho$(salt-free); the bottom 2 $\rho(Tl^+) - \rho(K^+)$. The solid and dotted lines are of lamellar spacing at 4.34 and 4.24 nm, respectively (Olah *et al.*, 1991).

gramicidin samples were given in (Olah *et al.*, 1991). If one is only interested in measuring the peak to peak distance PtP, normalization is unnecessary (Chen *et al.*, 1997).

The normalized electron density profiles of the DLPC bilayer containing gramicidin channels are shown in Figure 14.8a with K^+ or with Tl^+. The difference in electron density profile (Figure 14.8b) revealed a pair of symmetrically located ion-binding sites for monovalent cations at 0.96 (±0.03) nm from the midpoint of the gramicidin channel. Similarly, Figure 14.9 shows a pair of binding sites for divalent cations at 1.30 (±0.02) nm from the midpoint of the gramicidin channel. To date, the X-ray method is the only experimental technique capable of directly measuring the locations of the ion-binding sites in the gramicidin channel. These ion-binding sites have been crucial for the molecular dynamics studies of the gramicidin channel (Roux, Prod'hom and Karplus, 1995).

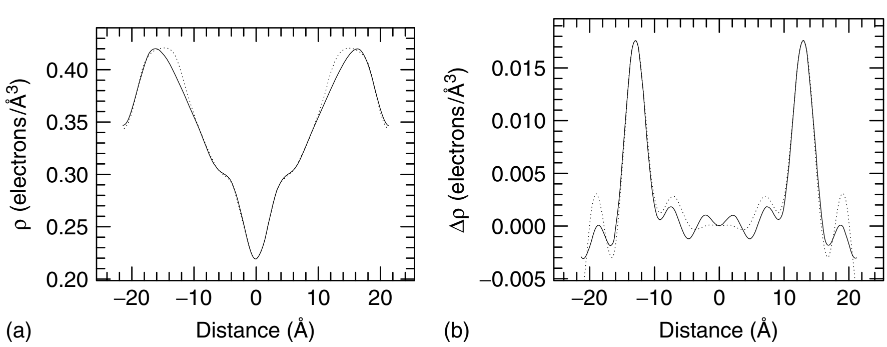

Fig. 14.9 (a) Normalized electron density profiles of gramicidin–DLPC bilayers with Ba^{2+} (dotted line) and with Mg^{2+} (solid line), obtained from the diffraction amplitudes of lamellar spacing 4.28 nm. (b) Difference in electron density profiles $\rho(Ba^{2+}) - \rho(Mg^{2+})$ at lamellar spacings 4.28 and 4.44 nm (Olah *et al.*, 1991).

14.3.2
Hydrophobic Matching between Lipids and Proteins

The gramicidin channel is a head-to-head hydrogen bonded dimmer. In lipid bilayers, the channel undergoes association–dissociation (dimer–monomers) reactions. As a result, a channel has a well-defined lifetime (its survival probability exponentially decreases in time) that can be measured accurately by single-channel conductance experiment (Hladky and Haydon, 1970, 1984). It has been shown that the gramicidin channel lifetime decreases with increasing thickness of lipid bilayer (Elliott *et al.*, 1983). This membrane thickness effect was explained as a consequence of hydrophobic matching between the gramicidin channel and the lipid bilayer. When there is a hydrophobic mismatch between the channel and the unperturbed state of the lipid bilayer, the effect of hydrophobic matching would create a local deformation in the lipid bilayer according to the elasticity theory. This membrane deformation energy and its effect on the gramicidin channel lifetime have been calculated, and the result successfully explained the membrane thickness effect (Huang, 1986).

Hydrophobic matching, in which a transmembrane protein causes the surrounding lipid bilayer to adjust its hydrocarbon thickness to match the hydrophobic surface of the protein, is a commonly evoked hypothesis. However, direct experimental evidence is scarce. To test the hypothesis, gramicidin was incorporated, at 1 : 10 peptide–lipid ratio, in two lipid bilayers of different thickness: DLPC and dimyristoylphosphatidylcholine (DMPC). The bilayer thickness, PtP, with or without gramicidin, was measured by X-ray diffraction (Harroun *et al.*, 1999). As we can see from the result shown in Figure 14.10, the discussion of membrane thickness is complicated by its temperature and hydration dependence. In each temperature, PtP was measured as a function of the lamellar spacing *D* by varying the relative humidity (RH) surrounding the sample. (*D* can be measured accurately to ±0.01 nm, whereas the accuracy of commercial RH sensors is typically ±1.5%.) In the fluid phase of DMPC bilayers, PtP approaches a constant value at high *D* values (or as RH approaches full hydration). It is well known that each phospholipid, particularly those with saturated chains like DMPC, has a fluid–gel main transition

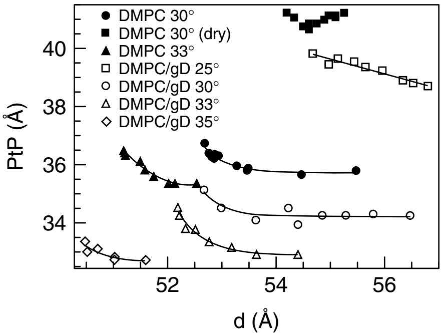

Fig. 14.10 Phosphate peak-to-phosphate peak (PtP) distance of the electron density profile as a function of lamellar spacing *D* for pure DMPC bilayers and DMPC bilayers containing gramicidin at the peptide-to-lipid ratio 1 : 10 (Harroun *et al.*, 1999).

temperature (~24 °C for DMPC). However, it would be a mistake to assume that DMPC containing gramicidin has the same transition temperature. In general, the transition temperature increases and broadens with inclusion of foreign molecules, but it is impossible to predict. Thus, part of the experiment was in finding that the transition temperature of gramicidin–DMPC 1 : 10 mixture extended over a range from 27 to 32 °C. In the fluid phase (≥32 °C) and near full hydration, the PtP was 3.53 nm for pure DMPC but 3.27 nm for the DMPC–gramicidin mixture (Harroun *et al.*, 1999). On the other hand, the PtP was 3.08 nm for pure DLPC but 3.21 nm for the DLPC–gramicidin mixture (Olah *et al.*, 1991; Chen *et al.*, 1997). Gramicidin apparently thickened DLPC and thinned DMPC toward a common thickness as expected by hydrophobic matching. The result is consistent with the effect of membrane thickness on the gramicidin channel lifetime (Elliott *et al.*, 1983; Huang, 1986).

14.3.3
Membrane Thinning Effect of Antimicrobial Peptides

In another example of measuring the membrane thickness, we investigated the molecular mechanism of antimicrobial peptides. Gene-encoded antimicrobial peptides act on the lipid matrix of cell membranes. Their bactericidal activities exhibit a so-called all-or-none concentration dependence, that is, little activity below a threshold concentration and quickly reaching the maximum activity as the concentration exceeds the threshold. To understand this phenomenon, we have performed experiments on the peptide–lipid systems with X-ray, neutron, oriented circular dichroism, and giant unilamellar vesicles (Huang, 2006). We found that above a concentration threshold the peptides form pores in the membranes. But the crucial data for understanding the mechanism came from the X-ray measurement of membrane thickness.

Representative peptides (alamethicin, magainin, protegrin, and melittin) were incorporated into various lipid bilayers (complete references in Huang (2006)). In each case the bilayer thickness was measured as a function of the peptide concentration (peptide–lipid molar ratio P/L), and in all cases the PtP decreased linearly with P/L below a threshold P/L^* (Figure 14.11). Above the threshold, PtP was constant. This indicates that the peptides initially bind to the lipid interface causing an area expansion, hence thinning the hydrocarbon region. Membrane thinning incurs an elastic energy proportional to the square of P/L. Hence, the energy level of inter-racial binding increases with P/L. As the peptide concentration increases over the threshold concentration P/L^*, the interfacial binding energy level surpasses the energy of pore formation. So, above the threshold all excessive peptides form pores, which if occuring in cell membranes cause cytolysis.

14.4
In-Plane Scattering

We now describe the method of measuring the distributions of proteins or protein assemblies in membranes. As an example, we use the X-ray diffraction taken from oriented stacks of lipid bilayers containing gramicidin channels (Yang *et al.*, 1999).

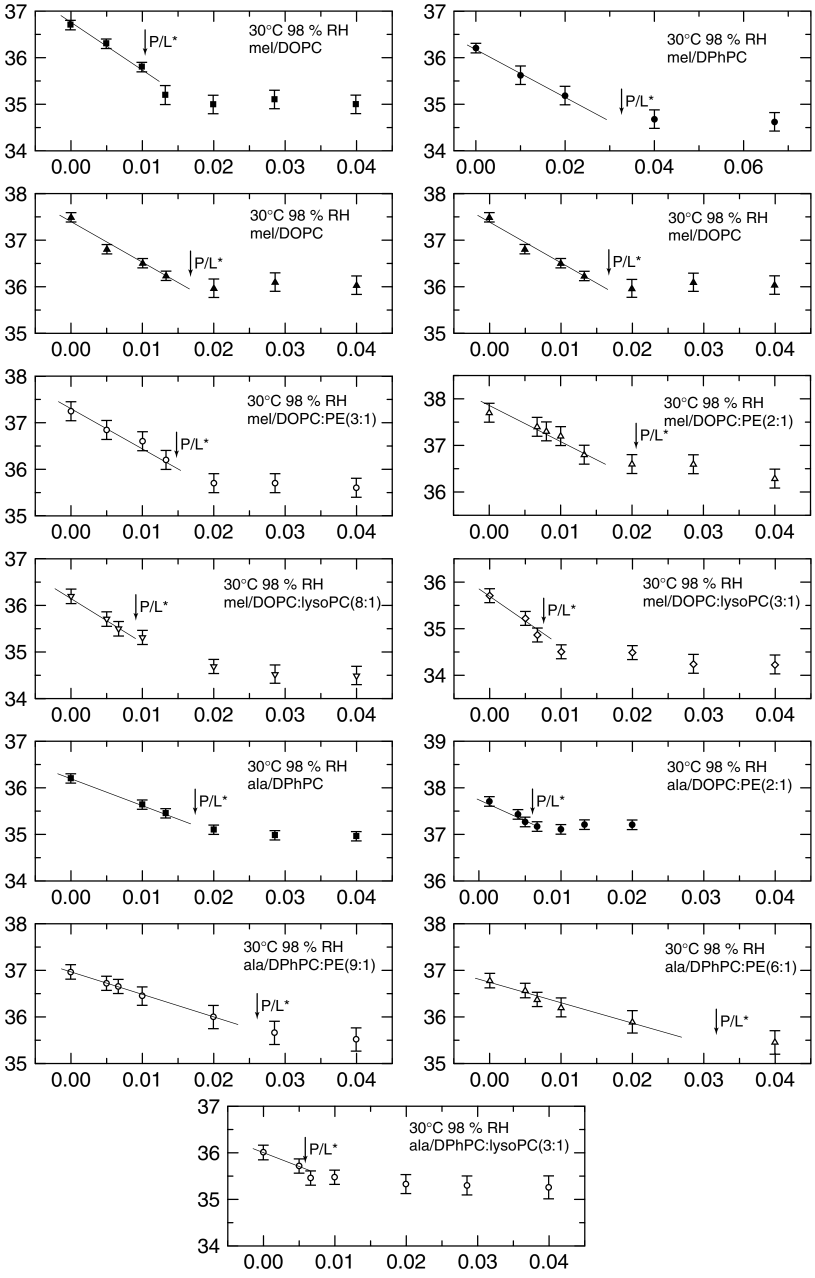

Fig. 14.11 Phosphate peak-to-phosphate peak (PtP) of lipid bilayers as a function of the peptide concentration P/L. Each panel shows a different peptide–lipid combination. P/L^* in each panel is the threshold concentration measured by oriented circular dichroism. At concentrations above P/L^* the peptides form pores in the membranes (Huang, 2006).

14.4.1
Scattering by Proteins Embedded in Fluid Multilayers

We start with X-ray scattering intensity $I(\boldsymbol{q})$ given by the following equation:

$$I(\boldsymbol{q}) = \left\langle \left|A(q)\right|^2 \right\rangle = \left\langle \left| \int \rho(\boldsymbol{r}) \exp(\mathrm{i}\boldsymbol{q} \cdot \boldsymbol{R}) d\boldsymbol{R} \right|^2 \right\rangle \quad (6)$$

where $A(\boldsymbol{q})$ is the scattering amplitude and $\rho(\boldsymbol{R})$ is the electron density at position $\boldsymbol{R}$ in the sample. In Eq. (6) a pre-factor representing the scattering intensity from an electron has been omitted for simplicity (Warren, 1969). We write $\rho(\boldsymbol{R}) = \rho_0(\boldsymbol{R}) + \phi(\boldsymbol{R})$ where $\rho_0(\boldsymbol{R})$ represents the density of pure lipid multilayers prepared without gramicidin, and $\phi(\boldsymbol{R})$ is the density contrast of gramicidin channels against the lipid background. Defining

$$A_0(q) = \int \rho_0(r) \exp(\mathrm{i}\boldsymbol{q} \cdot \boldsymbol{R}) d\boldsymbol{R},$$
$$A_\phi(q) = \int \phi(r) \exp(\mathrm{i}\boldsymbol{q} \cdot \boldsymbol{R}) d\boldsymbol{R} \quad (7),$$

we have,

$$I = \langle |A_0 + A_\phi|^2 \rangle = \langle |A_0|^2 \rangle + \langle |A_\phi|^2 \rangle + 2\langle \mathrm{Re}(A_0 A_\phi^*) \rangle \quad (8)$$

The contribution of A_0 has been described in Section 14.1.1. As illustrated in Section 14.2, the scattering amplitude of proteins is in the low-angle region normal to the bilayers' lamellar diffraction and does not overlap with the diffraction from lipid chains around ~14 nm^{-1}. Therefore, we may consider the scattering by $\phi(\boldsymbol{R})$ separately. We denote the positions of the centers of the gramicidin channels by $\boldsymbol{R}_n$, $n = 1, 2, \ldots, N$, so that $\phi(\boldsymbol{R}) = \sum_n \phi_c(\boldsymbol{R} - \boldsymbol{R}_n)$ where $\phi_c(\boldsymbol{R} - \boldsymbol{R}_n)$ is the density contrast for a gramicidin channel. Then the scattering intensity can be written in the form

$$I(q_z, q_r) = N|F_\phi(q_z, q_r)|^2 S(q_z, q_r) \quad (9)$$

with the structure factor $S(q_z, q_r)$ and the form factor $F_\phi(q_z, q_r)$ given by

$$S(q_z, q_r) = \frac{1}{N} \left\langle \left| \sum_n \exp(\mathrm{i}\boldsymbol{q} \cdot \boldsymbol{R}_n) \right|^2 \right\rangle \quad (10)$$

$$F_\phi(q_z, q_r) = \int \phi_c(\boldsymbol{R} - \boldsymbol{R}_n) \times \exp[\mathrm{i}\boldsymbol{q} \cdot (\boldsymbol{R} - \boldsymbol{R}_n)] d\boldsymbol{R} = F_{\mathrm{G}}(q_z, q_r) - F_{\mathrm{lb}}(q_z, q_r) \quad (11)$$

$F_{\mathrm{G}}(q_z, q_r)$ and $F_{\mathrm{lb}}(q_z, q_r)$ are, respectively, the form factor of the gramicidin channel and the form factor of a patch of lipid bilayer that would have filled the space occupied by the gramicidin channel. Note that the z-coordinate of $\boldsymbol{R}_n$ is discrete, denoted by mD, $m = 0, \pm 1, \pm 2, \ldots$ In this case the structure factor can be written as (Yang *et al.*, 1999)

$$S(q_z, \boldsymbol{q}_r) = 1 + \sum_m \exp(\mathrm{i}q_z mD) \int n_{0m}(\boldsymbol{r}) \times \exp(i\boldsymbol{q}_r \cdot \boldsymbol{r})\, d\boldsymbol{r} \quad (12)$$

where $\boldsymbol{r}$ is the two-dimensional coordinate in the plane parallel to the membranes. The correlation function $n_{0m}(\boldsymbol{r})d\boldsymbol{r}$ is defined as the average number of gramicidin channels within the area element d$\boldsymbol{r}$ at the position $\boldsymbol{r}$ in the mth bilayers relative to an arbitrarily chosen gramicidin channel in the zeroth bilayer.

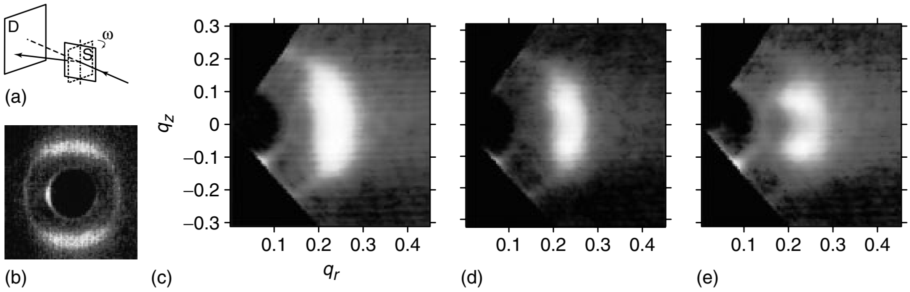

Fig. 14.12 (a) The diffraction geometry. The multilayers were 60° with respect to the detector. (b) The detector image of DLPC bilayers containing gramicidin at the peptide–lipid ratio 1 : 10 at 25 °C and >95% RH. (c) The detector image (a) was translated to the $q_z - q_r$ coordinates. (d) and (e) the diffraction pattern of the same sample at 90 and 80% RH, respectively (Yang *et al.*, 1999).

By symmetry $n_{0m} = n_{0-m}$. Expanding the sum in Eq. (12) and making use of the fact that the distribution of channels in a fluid bilayer is isotropic in the plane, we have

$$S(q_z, \mathbf{q}_r) = S(q_z, q_r) = S_{00}(q_r) + 2\cos \times (q_z D) S_{01}(q_r) + \cdots \qquad (13)$$

$$S_{0m}(q_r) = \delta_{0m} + \int [n_{0m}(r) - \overline{n}] \times J_0(q_r r) 2\pi r \, dr \qquad (14)$$

Note that in Eq. (13) all $S_{0m}(q_r)$ factors are multiplied by a q_z-dependent factor, except for the $S_{00}(q_r)$ term.

The distribution of gramicidin channels in a membrane is described by the radial distribution function $2\pi r n_{00}(r)\, dr$, which is the average number of channels within the ring of radius r and width dr, centered at an arbitrarily chosen channel. This function can be obtained from $S_{00}(q_r)$ by Bessel transform

$$2\pi r n_{00}(r) = 2\pi r \overline{n} + r \int [S_{00}(q_r) - 1] \times J_0(q_r r) q_r \, dq_r \qquad (15)$$

14.4.2
Radial Distribution Function of Protein in Membrane

Mixtures of lipids and gramicidin at the molar ratio of 10 : 1 were lyophilizied and then hydrated by water vapor (Huang and Olah, 1987). Approximately 5 mg of hydrated sample was sandwiched between two polished, SiO_2 coated beryllium plates (0.5 mm thick, 15 mm in diameter). The sandwiched samples were manipulated to rid of smectic defects (the procedures were described in Huang and Olah, 1987). The scattering pattern was recorded with the multilayers oriented at 60° with respect to the detector (Figure 14.12a). The detector image (Figure 14.12b) was translated to the (q_z, q_r) plane (Figure 14.12c). The scattering pattern of gramicidin is in a region free of the diffraction from the lipid multilayers. The data shown in Figure 14.12c was taken at RH >95%. The same sample was also measured at ~90% RH (Figure 14.12d) and at ~80% RH (Figure 14.12e).

Inter-bilayer correlations are usually absent when the multilayers are fully hydrated since the bilayers are well separated. However, this needs to be

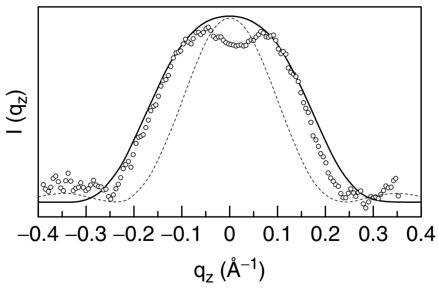

Fig. 14.13 The q_z-dependence of the diffraction pattern shown in Figure 14.12c. The data (o) were taken along the q_z coordinate at the value of q_r fixed at the maximum intensity. The solid line is the form factor of the gramicidin channel contrasted against the lipid background $|F_\iota(q_z, q_r)|^2 = |F_G(q_z, q_r) - F_{\mathrm{lb}}(q_z, q_r)|^2$. In contrast the dotted line is the form factor of the gramicidin channel $|F_G(q_z, q_r)|^2$. It shows that the contribution of the lipid background is important. The data show a small dip at the top indicating a small sign of inter-bilayer correlations. It implies that the sample was not quite fully hydrated (Yang *et al.*, 1999).

demonstrated before one uses the data to analyze the distribution of proteins in the membranes. This can be seen in the case of Figure 14.12c. Figure 14.13 shows that the q_z dependence of the scattering intensity $I(q_z, q_r)$ (Figure 14.12c) is the same as the q_z dependence of the form factor $|F_{phi}(q_z, q_r)|^2$, where the value of q_r is fixed at the peak value along the q_r axis. That means that according to Eq. (9) the structure factor $S(q_z, q_r)$ has no significant q_z dependence. Therefore, according to Eqs (14.12) and (14.13), $S(q_z, q_r)$ is essentially $S_{00}(q_r)$. All $S_{0\,m}(q_r)$, $m \neq 0$ terms in the expansion of $S(q_z, q_r)$ (Eq. (13)) vanish. Only under this condition one may obtain $S_{00}(q_r)$ by $S_{00}(q_r) = I(q_z, q_r)/(N|F_\phi(q_z, q_r)|^2)$. One can then use Eq. (15) to obtain the radial distribution function of proteins.

We now compare the distribution of gramicidin channels in DLPC and DMPC bilayers, both prepared at the peptide-to-lipid molar ratio of 1 : 10. Under the condition of no inter-bilayer correlations, the scattering intensities $I(q_z = 0, q_r)$ are shown in Figure 14.14: DMPC/gD at 20 °C (gel phase) and at 32 °C (fluid phase) and DLPC/gD at 25 °C (fluid phase). Their respective radial distribution functions are shown in Figure 14.15 (Harroun *et al.*, 1999). The distribution function rises from near zero at small r to a first maximum at the distance where there is a high probability for finding neighboring channels. This distance is the most probable nearest-neighbor separation between channels. Beyond this distance, $2\pi r n_{00}(r)$ oscillates below and above the average density curve $2\pi r\bar{n}$. The most interesting result is in the difference between DMPC/gD and DLPC/gD in the fluid phase. Apparently the channel–channel nearest-neighbor distance is smaller in DMPC (2.23 nm) than in DLPC (2.68 nm). Individual gramicidin channels diffuse randomly in the fluid membranes, but on an average the channels are 13% closer to each other in DMPC than in DLPC. In Section 14.3, we have seen that gramicidin channels caused a greater thickness change in DMPC than in DLPC because DMPC has a greater hydrophobic mismatch with the gramicidin channel than does DLPC. The thickness change around each channel creates a strain field in the lipid bilayer. This strain field creates an attractive membrane-mediated potential between gramicidin channels (Harroun *et al.*, 1999). As expected, the X-ray measurement showed that this attractive potential

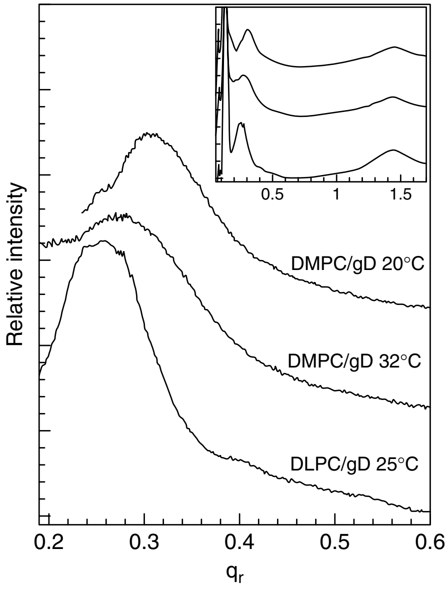

Fig. 14.14 X-ray in-plane scattering curves. The inset show (from top to bottom) the raw data of DMPC/gD (10 : 1) at 20 °C, DMPC/gD (10 : 1) at 32 °C, and DLPC/gD (10 : 1) at 25 °C. The main frame shows the in-plane scattering curves after removing the pure lipid background. These are the in-plane scattering curves of gramicidin (Harroun *et al.*, 1999).

is greater in DMPC than in DLPC. There have long been speculations that protein–lipid hydrophobic mismatch would cause membrane-mediated attractive interactions between proteins, and such interactions might be responsible for inhomogeneous lateral distributions of intrinsic membrane proteins and consequently the functional specialization of regions in cell membranes (Marcelja, 1976; Schroeder, 1977; Owicki and McConnell, 1979). As far as we know, the result shown in Figure 14.15 provided the first and only experimental evidence.

Finally a short note on inter-bilayer correlations. At lower hydration levels (Figure 14.12d and e), the q_z dependence of $I(q_z, q_r)$ shows undulations that are apparently different from the q_z dependence of $|F_\phi(q_z, q_r)|^2$ in Figure 14.7. This indicates existence of inter-bilayer correlations. Analyses of inter-bilayer correlations can be found in Yang *et al.*, 1999.

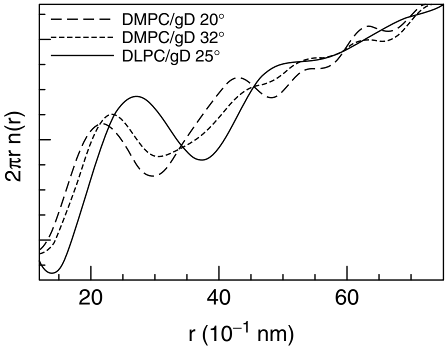

Fig. 14.15 Radial distribution functions obtained from the data shown in Figure 14.14. The position of the first peak gives the most probable nearest-neighbor separation between gramicidin channels in the bilayer (Harroun *et al.*, 1999).

14.5 Periodically Ordered Lattices of Lipid Structures

14.5.1 Method of Measurement and Data Reduction

As mentioned in Section 14.2, periodically ordered lattices of lipid assemblies (excluding the cubic phases) can be conveniently prepared on the surface of a solid substrate (a silicon wafer or a polished glass plate). The lattice constants of lipid assemblies are typically ∼5 nm, and their diffraction peaks tend to be limited within $<10\ \mathrm{nm}^{-1}$. The lattice domains in such samples are randomly oriented in the plane of the substrate. Therefore, with the exception of the reciprocal vectors normal to the substrate (z-axis), all Bragg peaks form rings parallel to the plane of substrate (the x–y plane). With X-rays of ∼8–15 keV incident at a grazing angle, the Ewald sphere intercepts the majority of the Bragg rings (reflection image in Figure 14.16). Each Bragg ring will be registered as a diffraction peak on the detector. However, there are two types of Bragg peaks not recorded by the grazing angle reflection. First, at a fixed incident angle, the Ewald sphere intersects the q_z axis twice: one at the origin of reciprocal space and another at the specular angle. Therefore, the diffraction pattern at one incident angle does not include the Bragg peaks on the z-axis. These peaks are measured by rotating the sample continuously to vary the incident angle, so that the intercept of the Ewald sphere with the z-axis moves along this axis at constant speed (ω-scan in Figure 14.16). Secondly, the Bragg rings with $q_z = 0$ are inaccessible by

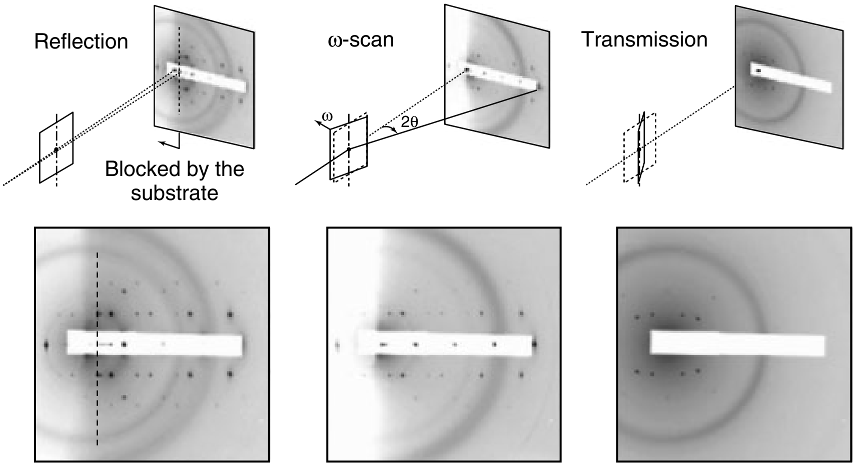

Fig. 14.16 A complete diffraction pattern for a nonlamellar phase is obtained by a combination of three recordings. (a) Reflection: X-ray beam was incident at a grazing angle (0.7°) to the substrate. On the detector, the region to the left of the dashed line was blocked by the substrate. The spot between the dashed line and (001) was the specular reflection. (b) ω-scan: this was the conventional $\omega - 2\theta$ scan along the q_z axis. The intensities accumulated during the ω-scan at the peak positions off the q_z axis were not suitable for analysis. (c) Transmission: the incident angle was −30°. Each detector image was the average of two 120-seconds exposures (Yang and Huang, 2003).

reflection, because, in practice, reflection always imparted a finite q_z. These Bragg peaks on the x–y plane can be recorded by transmission diffraction (transmission image in Figure 14.16). These three recordings combine to give a complete diffraction pattern for a periodically ordered lattice on a substrate. However, if one takes into account the symmetry of the lattice, the recording can be simplified for some lattices. For example, one grazing angle reflection is sufficient to include the complete diffraction pattern for an inverted hexagonal phase.

Removing the background from the diffraction peaks needs to be done with care. Usually the intensities of the diffraction peaks are integrated directly using the detector image. One may fit each peak with a two-dimensional Gaussian function plus a background and then integrate the function without the background. Or, one may integrate the intensities first in one direction (e.g. parallel to the substrate) over a width slightly wider than the apparent peak widths. The result is plotted along the substrate normal. On this one-dimensional profile the background is obtained by using the intensities between peaks and extrapolated into the peak regions. After the background subtraction, each peak is integrated. It would be reassuring if the two methods give the same result.

The procedure for data reduction starts with the translation of a vector (P_x, P_y, P_z) in the detector frame to a vector $(P^s{}_x, P^s{}_y, P^s{}_z)$ in the sample frame. (i) Use a standard sample (e.g. silver behenate, $D = 5.84$ nm) to determine the beam center O on the detector frame and the sample-to-detector distance $\overline{\mathrm{SD}}$. (ii) Determine the physical coordinates of each peak on the detector (P_x, P_z) (P_x is parallel to the plane of substrate). (iii) The diffracted beam vector **S** is defined by the direction $(P_x, \overline{\mathrm{SD}}, P_z)$ in the detector frame. (iv) Determine the incident angle α from the reflection point. Then the direction of **S** in the sample frame is given by

$$\begin{aligned}\begin{pmatrix} P^s_x \\ P^s_y \\ P^s_z \end{pmatrix} &= |P^s| \begin{pmatrix} S_x \\ S_y \\ S_z \end{pmatrix} \\ &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\alpha & \sin\alpha \\ 0 & -\sin\alpha & \cos\alpha \end{pmatrix} \\ &\quad \times \begin{pmatrix} P_x \\ \overline{SD} \\ P_z \end{pmatrix} \qquad (16)\end{aligned}$$

We also define the following angles: $(S_x, S_y, S_z) = (\cos\nu \ \sin\gamma,\ \cos\nu \ \cos\gamma,\ \sin\nu)$. The scattering vector in the sample frame is $q = (q_x, q_y, q_z) = (2\pi/\lambda)$ $[-(S_x, S_y, S_z)](0, \cos\alpha, -\sin\alpha)$.

The integrated intensity for a Bragg peak E is related to unnormalized form factor squared $|F|^2$ by $E = I_0|F|^2 C_\mathrm{P} C_\mathrm{L} C_\mathrm{abs} C_\mathrm{geo} \Delta T$ (Table 14.1). The reduction includes the polarization factor C_P, the Lorentz factor C_L, the absorption factor C_abs, and a factor for diffraction volume C_geo. The principles for all these factors can be found in Warren's book (Warren, 1969). The values of these factors are given in Table 14.1. The last factor ΔT is for relative normalization between the reflection recording and the ω-scan recording. Given the same incident beam intensity, if the reflection is recorded for a time ΔT in seconds, the equivalent factor for the ω-scan is $2\pi/\Omega$ where Ω is the angular speed of ω-rotation in rad s^{-1} (Yang and Huang, 2003; Ding *et al.*, 2005). This allows us to obtain the relative magnitude of the diffraction amplitude $|F|$ for all Bragg peaks.

Tab. 14.1 Formula for data reduction $E = I_0 |F|^2 C_P C_L C_{\mathrm{abs}} C_{\mathrm{geo}} \Delta T$.

Reflection	**ω-scan**
$C_p = \sin^2 \psi$	$C_p = \cos^2 2\theta$
$C_L = \dfrac{1}{\cos\alpha \cos\nu \sin\gamma}$	$C_L = 1/\sin 2\theta$
$C_{\mathrm{abs}} = \dfrac{1 - \exp\left[-\mu a \left(\dfrac{1}{\sin\nu} + \dfrac{1}{\sin\alpha}\right)\right]}{\mu a \left(\dfrac{1}{\sin\nu} + \dfrac{1}{\sin\alpha}\right)}$	$C_{\mathrm{abs}} = \dfrac{[1 - \exp(-2\mu a/\sin\theta)]\sin\theta}{2\ \mu a}$
$C_{\mathrm{geo}} = \dfrac{b/\sin\alpha}{w}$ or 1 if greater than 1	$C_{\mathrm{geo}} = \dfrac{b/\sin\alpha}{w}$ or 1 if greater than 1
ΔT	$2\pi/\Omega$

Notations (also applicable to neutron diffraction except for noted): 2θ, the angle between the incident beam and the diffracted beam; ψ, the angle between the incident polarization vector and the scattered beam; $\alpha = \omega$, the angle between the incident beam and the substrate surface (the $x - y$ plane); ν, the angle between the diffracted beam and the $x - y$ plane; γ, the angle between the in-plane $(x - y)$ projection of incident beam and the in-plane projection of the diffracted beam; μ, the linear absorption coefficient of sample; μ_s, the linear absorption coefficient of substrate; a, the sample thickness; and a_s, the substrate thickness.

The polarization factor C_P is for X-ray diffraction only.
C_{abs} in the table is for reflection geometry. For transmission geometry the absorption correction is

$$C_{\mathrm{abs}} = \exp\left[-\frac{\mu_s a_s + \mu a}{\sin\alpha}\right] \frac{1 - \exp\left[-\mu a \left(\dfrac{1}{\sin\nu} - \dfrac{1}{\sin\alpha}\right)\right]}{\mu a \left(\dfrac{1}{\sin\nu} - \dfrac{1}{\sin\alpha}\right)}$$

C_{geo} is the ratio of the length of the beam footprint $b/\sin\alpha$ over the length of the sample w (b is the beam width). ΔT is the scan time. Ω is the angular velocity of the ω-scan.

14.5.2
Methods of Phase Determination

The unit cell structure of a lipid assembly prepared from a homogeneous mixture can be reasonably assumed to be centrosymmetric $\rho(\boldsymbol{r}) = \rho(-\boldsymbol{r})$. Then from the definition of diffraction amplitude

$$F(\boldsymbol{q}) = \int_{\mathrm{cell}} \rho(\boldsymbol{r}) \exp(\mathrm{i}\boldsymbol{q} \cdot \boldsymbol{r})\, d\boldsymbol{r} \qquad (17)$$

one can easily show that $F(\boldsymbol{q}) = F^*(\boldsymbol{q})$. In other words, $F(\boldsymbol{q})$ is real and its phase is either 0 or π, or $F(\boldsymbol{q})$ is either positive or negative. At first glance, the phase problem seems simple. Given a finite number n of diffraction amplitudes, there are only 2^n possible phase combinations and one of them must be right. This might be a comforting thought, but it is sometimes difficult to pick the correct one by inspecting all possible combinations even in the case of lamellar diffraction (Wang *et al.*, 2006).

The two methods described below have recently been used with some success.

14.5.2.1 **Swelling Method and Pattern Recognition Method (With an Example in the Rhombohedral Phase)**

One of the most interesting discoveries concerning lipidic structures is the rhombohedral phase (Yang *et al.*, 2000). In Section 14.4 we described gramicidin channels embedded in oriented stacks of lipid bilayers and saw that the channels developed inter-bilayer correlations when the hydration level decreased. The same phenomenon occurred when the peptide-induced transmembrane pores were present in membranes (Yang *et al.*, 2000), and in these cases the inter-bilayer correlations eventually developed into long-range correlations. The pores formed a lattice of rhombohedral symmetry (space group $R\bar{3}$). Subsequently it was found that not only peptide-induced pores formed this lattice, pure lipid bilayers with negative spontaneous curvatures also formed this lattice in dehydrated condition (Yang and Huang, 2002; Yang *et al.*, 2003). Thus the rhombohedral phases seem to provide a common lattice for many different lipidic structures.

A rhombohedral lattice consists of hexagonal layers, stacked up in the ABCABC... fashion, similar to face-centered cubic (As expected, the hexagonal layers are always parallel to the surface of the substrate.). Between the hexagonal layers are intercalating layers of water. In some cases, the rhombohedral lattices allow a variation of the vertical lattice constant in response to a change of hydration level. This is called *swelling*, and the swelling method of phase determination could be used, similar to the lamellar phases described in Section 14.3. Here we describe an example of solving the phase problem for a rhombohedral lattice using the swelling method.

The rhombodedral diffraction pattern in Figure 14.16 is on a lattice described by the set of reciprocal vectors $\boldsymbol{b}_1 = (1/a, 1/\sqrt{3}a, -2/3c)$, $\boldsymbol{b}_2 = (0, 2/\sqrt{3}a, -1/3c)$, and $\boldsymbol{b}_3 = (0, 0, 1/c)$ indexed by (h, k, ℓ), which correspond to the crystal axes $\boldsymbol{a}_1 = (a, 0, 0)$, $\boldsymbol{a}_2 = (-a/2, \sqrt{3}a/2, 0)$, and $\boldsymbol{a}_3 = (a/2, a/2\sqrt{3}, c)$. $\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3$ define the primitive unit cell. a and c are the hexagonal and vertical lattice constants, respectively. Equivalently, the lattice is described by the reciprocal vectors $\boldsymbol{B}_1 = (1/a, 1/\sqrt{3}a, 0)$, $\boldsymbol{B}_2 = (0, 2/\sqrt{3}a, 0)$, and $\boldsymbol{B}_3 = (0, 0, 1/3c)$ indexed by (H, K, L) and the crystal axes $\boldsymbol{A}_1 = (a, 0, 0)$, $\boldsymbol{A}_2 = (-a/2, \sqrt{3}a/2, 0)$, and $\boldsymbol{A}_3 = (0, 0, 3c)$. The cell defined by $\boldsymbol{A}_1, \boldsymbol{A}_2, \boldsymbol{A}_3$ contains three primitive unit cells positioned at $(0, 0, 0)$, $(a/2, a/2\sqrt{3}, c)$, and $(0, a/\sqrt{3}, 2c)$. (H, K, L) indices are used in this article.

The detected Bragg peaks for the rhombohedral phase of the lipid diphytanoyl-phophatidylcholine (DPhPC) are shown in Figure 14.17. By the same principle described in Section 14.3.1, the relative phases of the diffraction amplitudes along each vertical column a, b, c, and d in Figure 14.17 can be phased by the swelling method (Yang and Huang, 2003).

After the relative phases within each column are determined, there are 2^3 (8) possible choices for the relative phases between the four columns. We can narrow the choices by using a pattern recognition method proposed by Luzzati and his collaborators (Mariani *et al.*, 1988). This method recognizes the fact that the basic structural element of lipid in water is the lipid monolayer. A change of the structure of a lipid–water system is

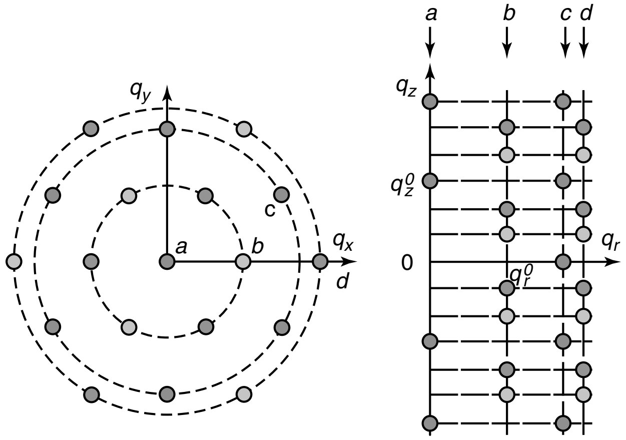

Fig. 14.17 The reciprocal lattice of rhombohedral symmetry on the $q_x - q_y$ plane (left) and the diffraction peaks detected on the $q_z - q_r$ plane (right). The reciprocal lattice of rhombohedral symmetry is composed of a stack of hexagonal layers stacked up in the ABCABC... sequence (A green, B blue, C red). In the $q_z - q_r$ plane are the four columns of the observed diffraction peaks. In Figure 14.18, the swelling method was applied to each set of the peaks having the same (H, K) (same color): column $a(H = 0, K = 0)$, $b(1, 0)$, $c(1, 1)$, and $d(2,0)$. The set of red peaks and the set of blue peaks in each of column b and d are equivalent by centrosymmetry (Yang and Huang, 2003). (Please find a color version of this figure on the color plates.)

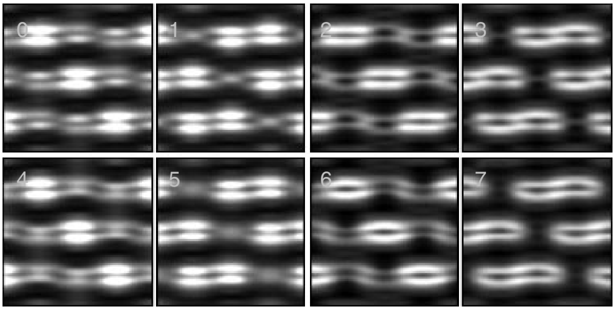
a rearrangement of the lipid monolayers. Therefore, if a lipid–water system has more than one structures, the different structures should have comparable electron density contrast histograms $H(\Delta\rho)$. For example, the structure of DPhPC in the L_α phase was known (Hung *et al.*, 2000) and so its $H(\Delta\rho)$ could be used as a reference. For the rhombohedral phase, we computed $H(\Delta\rho)$ for each of the eight possible choices of relative phases and compared the results with that of the L_α phase. For practical purposes, the method was carried out by computing the fourth moment $\langle(\Delta\rho)^4\rangle$ following the procedure of Mariani *et al.*, 1988

$$\langle(\Delta\rho)^4\rangle = \frac{\displaystyle\sum_{H,K,L}\left|\sum_{H',K',L'} F(\boldsymbol{q}_{H'-H,K'-K,L'-L})F(\boldsymbol{q}_{H',K',L'})\right|^2}{\left(\displaystyle\sum_{H,K,L} F(\boldsymbol{q}_{H,K,L})\right)^2} \tag{18}$$

Among the eight possible choices (Figure 14.19), two with $\langle(\Delta\rho)^4\rangle = 2.610$ and 2.640 are closest to the value of the L_α



Set #	Relative phase	$<(\Delta p)^4>$
0	++++	4.163
1	+−++	3.625
2	++−+	3.013
3	+−−+	2.610
4	+++−	4.416
5	+−+−	3.550

Fig. 14.18 $\langle(\Delta\rho)^4\rangle$ for the eight possible choices of relative phases are shown in the table on the right. The corresponding electron density maps are shown on the left. The choice 3 and 7 are closest to the value of the L_α phase, which has $\langle(\Delta\rho)^4\rangle = 1.750$. The electron density maps of choice 3 and 7 are very similar, both showing a stalk structure. However, upon close examination, the electron density map of the choice 3 shows somewhat uneven densities for the lipid headgroup along the lipid monolayer (need a close inspection of the density map). Therefore, the choice 7 is considered the most reasonable (Yang and Huang, 2003).

phase, which has $\langle(\Delta\rho)^4\rangle = 1.750$. The electron density distributions of these two choices (3 and 7 in Figure 14.18) are very similar, both show a stalk structure. However, upon close inspection, we found that the choice 3 produced somewhat uneven electron densities in the lipid headgroup region along the monolayers. The most reasonable choice of phases (7 of Figure 14.18) gave the electron density distribution

$$\rho(\boldsymbol{r}) = \frac{1}{V} \sum_{H,K,L} F(q_{H,K,L}) \cos(\boldsymbol{q}_{H,K,L} \cdot \boldsymbol{r}) \tag{19}$$

as shown in Figure 14.19.

The unit cell structure shown in Figure 14.19 suggests that two bilayers under the osmotic pressure merged into an hourglass-shaped structure called a *stalk* (Yang and Huang, 2002). The discovery of this lipid structure validated the stalk-pore hypothesis for membrane fusion (Chernomordik and Kozlov, 2005). This ended the long-time dispute about the mechanism of biomembrane fusion, whether it is lipidic in nature (stalk-pore hypothesis) or it is the proteins that play the dominant role and only make way for lipids at some point late in the process (protein pore hypothesis).

14.5.2.2 Multiwavelength Anomalous Dispersion Method (With Examples in Hexagonal, Distorted Hexagonal, and Rhombohedral Phases)

In protein crystallography the most reliable phase-determining method is the method of multiwavelength anomalous dispersion (MAD) (Grossmann and Arnold, 2001). In this method, one uses an equation relating three quantities, that is, the magnitude of the normal diffraction amplitude of the host molecules, the magnitude of the normal diffraction amplitude of the anomalous atoms, and the relative phase angle between the two amplitudes, with coefficients that are wavelength dependent. A set of diffraction measurements are then recorded at wavelengths below and above the absorption edge of the anomalous atom so as to vary these coefficients as much as possible in order to allow the three unknowns

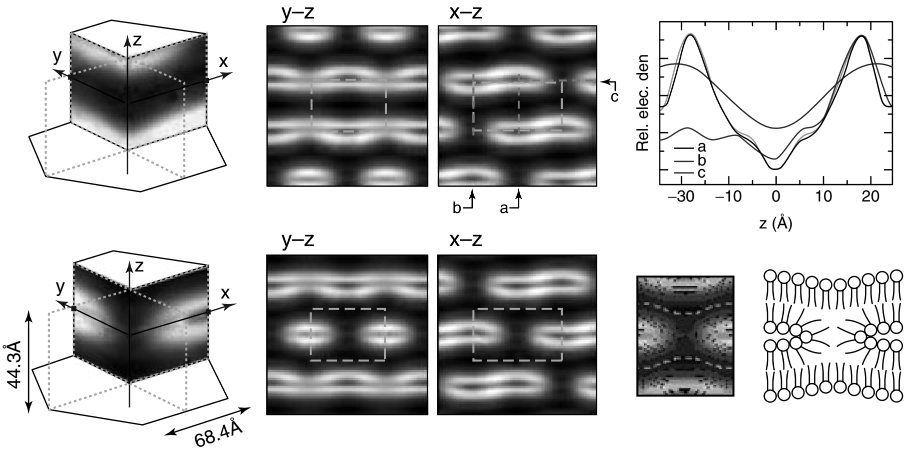

Fig. 14.19 Electron density distribution in the unit cell of the rhombohedral lattice (High density is white, low density is black.) (Top row): The unit cell was based on the phases determined by the swelling and pattern recognition methods. The stalk structure is not obvious in this unit cell. To its right are the density maps in the $y - z$ and $x - z$ planes. The dashed green rectangles are the boundaries of the unit cell in each map. On the $x - z$ map, the electron density profiles were taken along three lines a, b, and c, and shown in the top right panel. Also shown in the panel is a trans-bilayer density profile from the L_α phase. The bilayer portion in the rhombohedral phase remained very close to the L_α phase. (Bottom row): The unit cell was obtained by a translation from the previous one. A stalk structure appeared at the center of the cell. The maps on the $y - z$ and $x - z$ planes are shown to its right. The central part of the $y - z$ map is re-plotted with density contours on the right hand side, along with a cartoon of a talk where two lipid monolayers merged to form a hourglass structure (Yang and Huang, 2003). (Please find a color version of this figure on the color plates.)

to be determined. This standard method can be difficult for lipid samples since their sample thicknesses are usually not precisely known. The correction for X-ray absorption can be significantly uncertain if the absorption coefficient varies a great deal, such as below and above the absorption edge.

To alleviate the difficulty of absorption correction, we suggested a method of using only X-ray energies below the absorption edge, where the X-ray absorption coefficient is relatively small and almost independent of wavelength. It is possible to measure anomalous diffraction at 8–10 different X-ray energies below the edge so as to solve the unknowns by a straight-line fitting instead of solving nonlinear equations. We will demonstrate this method (Wang *et al.*, 2006) with brominated lipid 1,2-distearoyl(9,10-dibromo)-sn-glycero-3-phosphocholine, abbreviated as di18:0(9,10Br)PC, using the K absorption edge of Br to perform the MAD analysis.

It is well known that the absorption edge and the scattering factor near the edge are influenced by the chemical environment of the atom. Therefore, one needs to measure the anomalous scattering factor of the label atom in the actual sample. The absorption curve of di18:0(9,10Br)PC was measured over both sides of the Br K-edge 13.474 keV (Pan *et al.*, 2006). The absorption curve was then converted to the imaginary scattering factor f'' by using the theoretical values calculated by (Cromer and Libermann, 1970). The real part f' was calculated by the dispersion relation using the CHOOCH program by (Evans and Pettifer, 2001). Below the absorption edge, 10 energies were chosen with a step size $\Delta f' = 0.5$ (in the unit of electron) for each successive energy as shown in Table 14.2, where the values of f' and f'' of bromine atom are listed.

The diffraction amplitude from a system containing atoms of an element with anomalous scattering factor $f = f^n(q) + f'(\lambda) + \mathrm{i}f''(\lambda)$ is written as

$$\begin{aligned} F_\lambda &= \sum_j f_j^n \exp(\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}_j) \\ &\quad + \sum_k (f^n + f' + \mathrm{i}f'') \exp(\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}_k) \\ &= F_0 + \frac{f' + \mathrm{i}f''}{f^n} F_2 \end{aligned} \tag{20}$$

Tab. 14.2 Anomalous scattering factor at 10 sub-K edge X-ray energies (K edge at 13.474 keV).

n	En (eV)	f′	f″
1	13 470.7	−7.53	0.87
2	13 468.1	−6.98	0.68
3	13 464.8	−6.51	0.59
4	13 459.0	−5.99	0.54
5	13 449.8	−5.50	0.51
6	13 434.8	−5.00	0.50
7	13 409.1	−4.50	0.51
8	13 366.3	−4.00	0.52
9	13 294.1	−3.50	0.51
10	13 156.7	−3.00	0.52

where $\boldsymbol{q}$ is the X-ray scattering vector. f_j^n is the normal scattering factor of atom j at position r_j. The index j includes all atoms except for the anomalous atoms. The index k includes all the anomalous atoms. F_0 is the normal diffraction amplitude of the whole system. F_2 is the normal diffraction amplitude of the anomalous atoms alone. We will assume that the unit cell of the lipid structure is centrosymmetric, so that both F_0 and F_2 are real (rather than complex) quantities and their phases are the signs of the amplitudes. The subsequent analysis will test whether this assumption is valid. From Eq. (20), we have

$$|F_\lambda|^2 = \left(F_0 + \frac{f'}{f^n}F_2\right)^2 + \left(\frac{f''}{f^n}\right)^2 F_2^2 \tag{21}$$

However, the second term is about 1% of the first term, because at energies below the absorption edge the value of f'' is ~0.5, which is about 10% of $|f'|$ (Table 14.2). Therefore, we have the approximate relation

$$|F_\lambda| \approx \pm\left(F_0 - \frac{|f'|}{f^n}F_2\right) \tag{22}$$

where we have replaced f' by $-|f'|$, since f' is negative below the absorption edge.

The experimental value $|F_\lambda|$ is then plotted against $|f'|/f^n$ for each peak. If the data for every peak satisfy a linear relation, we may conclude that the method is validated. Since Eq. (22) is the combined consequence of (i) both F_0 and F_2 are real quantities and (ii) Eq. (21) is linearized to Eq. (22), the agreement with the data implies that both the assumption of centrosymmetry and the assumption of linear approximation are valid. From the linear plot, one finds the magnitude

$|F_0|$ from the intercept of the fitted line; the magnitude $|F_2|$ from the magnitude of the slope; and the sign of $-F_0/F_2$ from the sign of the slope.

This MAD analysis reduces the phase problem of the whole system (F_0) to the phase problem of the label atoms alone (F_2). The latter problem is much simpler than the original phase problem. And once the phases of F_2's are determined, so are those of F_0's.

Example 1: Hexagonal Phase The inverted hexagonal phase is the simplest nonlamellar phase, yet the phase problem of its diffraction is still very difficult (Turner and Gruner, 1992). This system was the first example investigated by the MAD method described above (Pan *et al.*, 2006). The mixture of di18:0(9,10Br)PC and cholesterol (in 2 : 1 ratio) is in the inverted hexagonal (H_{II}) phase below 44% RH at 25 °C. Figure 14.20a

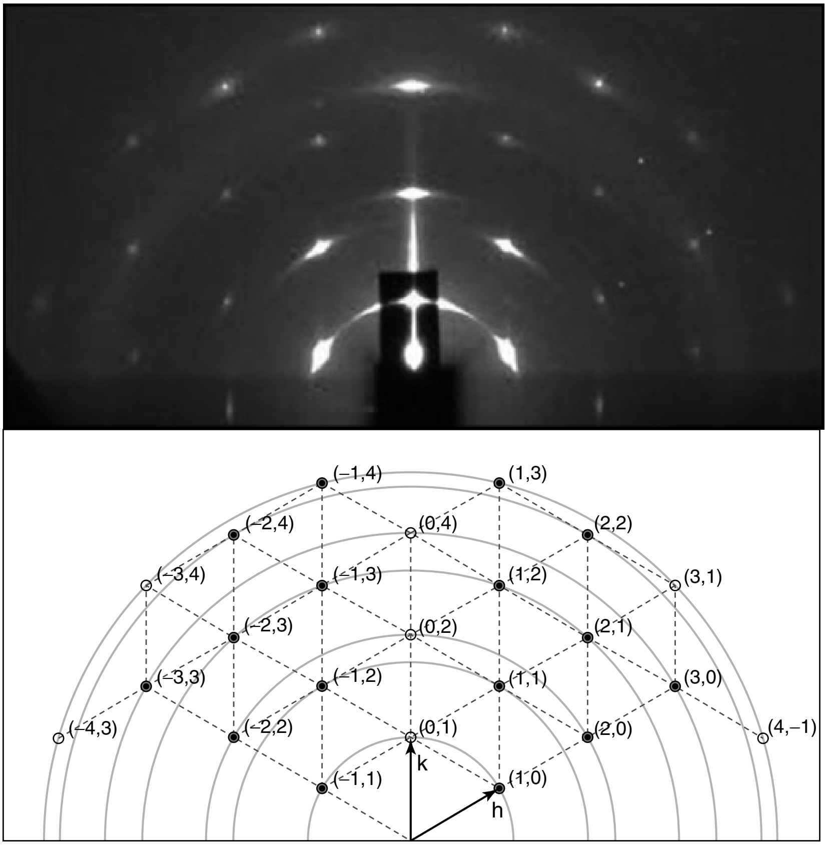

Fig. 14.20 (top) Diffraction pattern of the inverted hexagonal phase measured by reflection. The mixture of di18:0(9,10Br)PC and cholesterol (in 2 : 1 ratio) was prepared in an aligned lamellar phase in high humidity on a solid substrate, and then dehydrated to below 44% RH. (bottom) The detected Bragg peaks on a hexagonal reciprocal lattice. The peaks shown as solid circles were measured and analyzed. The lattice points at open circles are related to solid circles by symmetry (Pan *et al.*, 2006).

shows its diffraction pattern. Anomalous diffraction was measured at eight energies below the Br K-edge. Taking into account of the hexagonal symmetry, the diffraction pattern (Figure 14.20b) gave seven independent peaks. For each independent peak, the measured value $|F_\lambda|$ was plotted against $|f'|/f^n$ (Figure 14.21), which showed linearity within the experimental errors. From the linear fits, we obtained $|F_0|$, $|F_2|$, and the sign of the $-F_0/F_2$. The advantage of the MAD method is that we can work with the simpler distribution of bromine atoms alone (i.e. F_2) rather than with the distribution of the whole lipid (F_0).

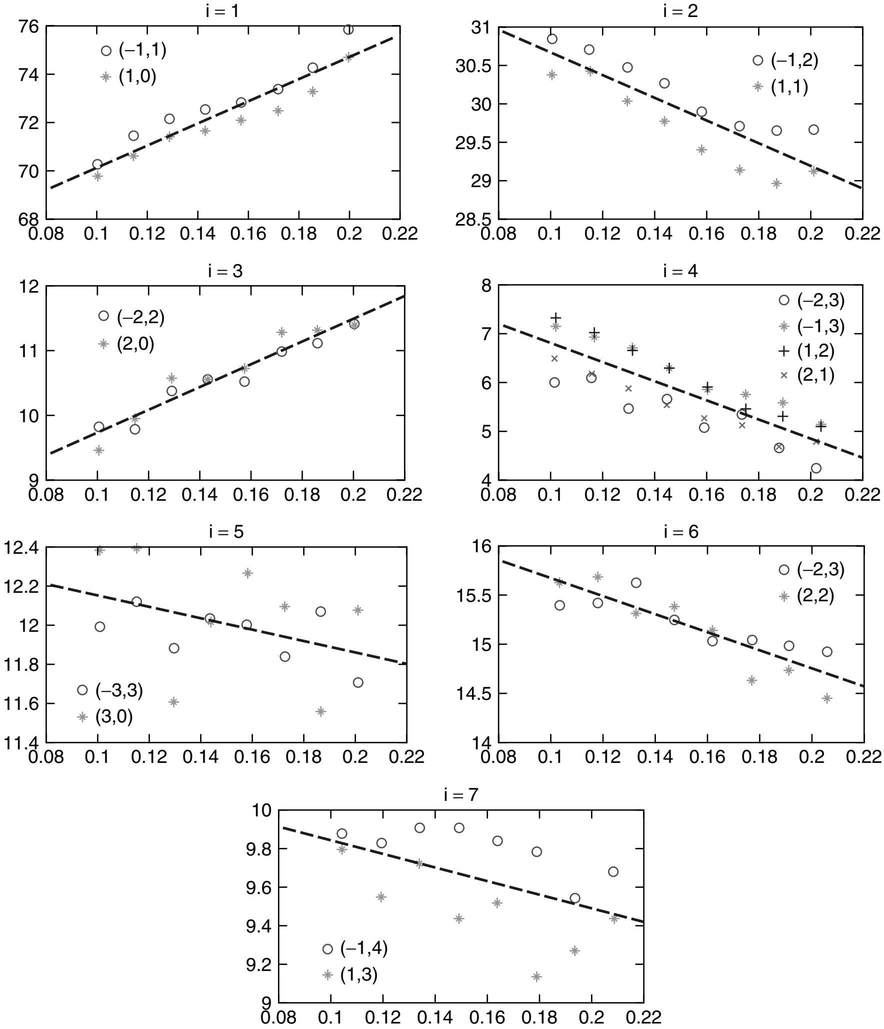

Fig. 14.21 The MAD analysis. For each panel, the ordinate is $|F_\lambda|$ and the abscissa is $|f'_\lambda|/f^n$. From the slope and intercept of the linear fit, we obtain $|F_0|$ and $|F_2|$ and the ratio F_0/F_2 (Pan *et al.*, 2006).

We solved the phase problem by modeling the distribution of bromine atoms. First, the Patterson map was constructed

$$P(r,\theta) = \sum_{(h,k)} |F_2(h,k)|^2 \times \cos\left\{\frac{2\pi}{D} r\left[\left(\frac{\sin\theta}{\sqrt{3}} + \cos\theta\right) \times h + \left(\frac{2}{\sqrt{3}}\sin\theta\right) k\right]\right\} \tag{23}$$

as shown in Figure 14.22. The fact that the Patterson function contains only one single peak implies that the Br distribution is localized at one radius and the width of the peak indicates the width of the Br distribution around that radius. Therefore, we built a model as a circular ring of Br distribution around the center of the unit cell. In a reference unit cell, the model is defined by

$$G[x_c, y_c] = \exp\left[\frac{-\left(\sqrt{(r\cos\theta - x_c)^2 + (r\sin\theta - y_c)^2} - r_0\right)^2}{2\sigma^2}\right] \tag{24}$$

where (r,θ) are the polar coordinates with the origin at the center of the reference unit center. $[x_c, y_c]$, referred to the same origin, are the coordinates of the center of a unit cell, which is either the reference unit cell or one of its adjacent unit cells. Within each unit cell, Br atoms are radially Gaussian-distributed, peaked at the radius r_0 with a width σ. Equation (23) describes the Br distribution in an isolated unit cell. To obtain the Br distribution in a lattice, we need to include the density contribution of the six adjacent unit cells, because the distribution defined by Eq. (23) spreads beyond the boundary of the unit cell. Thus the electron density measured by X-ray diffraction in the [0,0] unit cell is calculated from

$$\begin{aligned}\rho_{\text{mod}}^{\text{Br}}(r,\theta) = {} & G[0,0] + G[D,0] \\ & + G\left[\frac{D}{2}, \frac{\sqrt{3}D}{2}\right] \\ & + G\left[-\frac{D}{2}, \frac{\sqrt{3}D}{2}\right] \\ & + G[-D,0] \\ & + G\left[-\frac{D}{2}, -\frac{\sqrt{3}D}{2}\right] \\ & + G\left[\frac{D}{2}, -\frac{\sqrt{3}D}{2}\right]\end{aligned} \tag{25}$$

The model amplitudes are then calculated by

$$F_{\text{mod}}^{\text{Br}}(h,k) = \int\!\!\int_{r,\theta} \rho_{\text{mod}}^{\text{Br}}(r,\theta) \times \cos\left\{\frac{2\pi}{D} r\left[\left(\frac{\sin\theta}{\sqrt{3}} + \cos\theta\right) h + \left(\frac{2}{\sqrt{3}}\sin\theta\right) k\right]\right\} r\,dr\,d\theta \tag{26}$$

where the integration is over one unit cell. We adjusted the model parameters r_0 and σ until we obtained the best fit between the model amplitudes $|F_{\text{mod}}^{\text{Br}}(h,k)|$ and the seven experimental amplitudes $|F_2(h,k)|$ by maximizing the T function

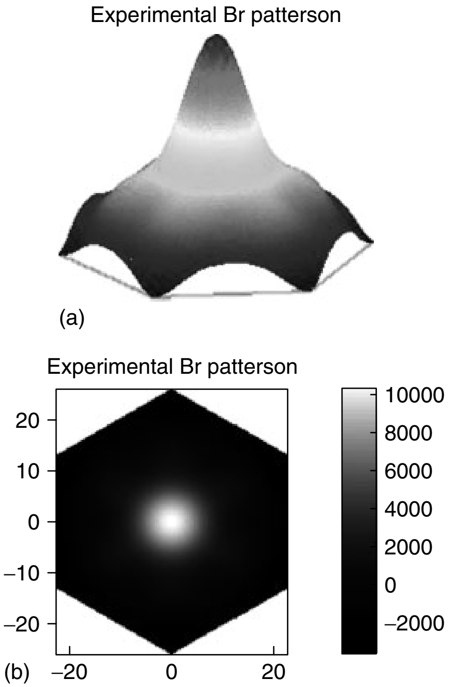

Fig. 14.22 The Patterson function for the bromine distribution: (a) 3D view and (b) 2D top view. The horizontal x, y coordinates are in the unit of Å. The vertical scale for the value of the Patterson function is arbitrary (Pan *et al.*, 2006).

(Pannu and Read, 1996; Saldin *et al.*, 2001)

$$T = \frac{\left[\sum_i (1/\varepsilon_i^2)|F_i^{\text{exp}}| \cdot |F_i^{\text{mod}}|\right]^2}{\sum_i (1/\varepsilon_i^2)(F_i^{\text{exp}})^2 \cdot \sum_i (1/\varepsilon_i^2)(F_i^{\text{mod}})^2} \tag{27}$$

where ε_i is the standard deviation for extracting F_i^{exp} from the raw data during the MAD analysis. The value of T is ≤ 1, with 1 being the perfect agreement between model and experiment. Our best fit gave a $T = 0.96622$. It is possible to refine the model to improve the T function to 0.97229 (Pan *et al.*, 2006) but it did not change the phases determined from the initial fit. These phases were then used to construct the experimental electron density distribution for the Br atoms as well as for the whole lipids (Figure 14.23) by the equation,

$$\rho_{\text{exp}}(r, \theta) = \sum_{(h,k)} F_{\text{exp}}(h, k) \times \cos\left\{\frac{2\pi}{D} r\left[\left(\frac{\sin\theta}{\sqrt{3}} + \cos\theta\right) h + \left(\frac{2}{\sqrt{3}}\sin\theta\right) k\right]\right\} \tag{28}$$

The undulation of Br distribution around the ring (Figure 14.23) was observed for the first time, and it contained useful information. This was due to confining a circular lipid tube in a hexagonal pipe. The inverted hexagonal phase has been used to study the chain packing in a hydrophobic interstice where three monolayers meet. Hydrophobic interstices are of great interest, because they

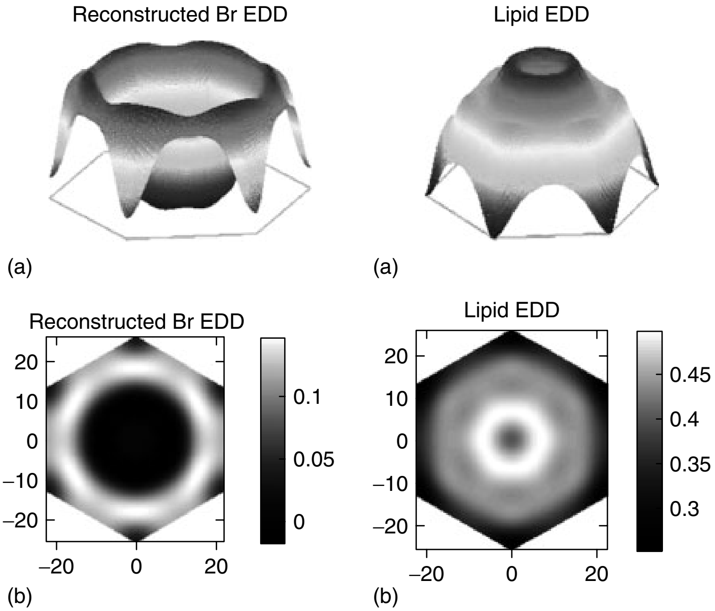

Fig. 14.23 (Left) Electron density distribution of bromine atoms reconstructed from the diffraction amplitudes: (a) 3D view and (b) 2D top view. (Right) Electron density distribution of the 2 : 1 mixture of di18:0(9-10dibromo)PC and cholesterol in a unit cell of the inverted hexagonal phase: (a) 3D view and (b) 2D top view. The horizontal x, y coordinates are in the unit of Å. The vertical scale for the electron density is e Å^{-3} (Pan *et al.*, 2006).

occur in the intermediate states of membrane fusion. It is generally believed that chain packing in such a region is energy costly. Consequently it has been speculated that the inverted lipid tube is likely to deviate from a circular shape, and the chain density distribution might be nonuniform. The bromine distribution obtained from the MAD analysis provided the information for the chain packing in the hexagonal unit cell. The intensity of the bromine distribution is undulated around the unit cell. The analysis shows that the lipid chains pack the hexagonal unit cell at constant volume per chain, with no detectable effect from a high-energy interstitial region (Pan *et al.*, 2006).

Example 2: Distorted Hexagonal Phase The mixture of di18:0(9,10Br)PC and cholesterol (in 2 : 1 ratio) studied above also exhibited a distorted hexagonal ($H_{II\delta}$) phase between 44% and 60% RH at 25 °C. We solved the structure of its unit cell to examine the distributions of two lipid components in a monolayer of nonuniform curvature (Wang *et al.*, 2007). Recent experiments suggested that cholesterol and other lipid components of high negative spontaneous curvature facilitate membrane fusion. This is taken as evidence supporting the stalk-pore model of membrane fusion in which the lipid bilayers go through intermediate structures of high curvature. How do the high-curvature lipid

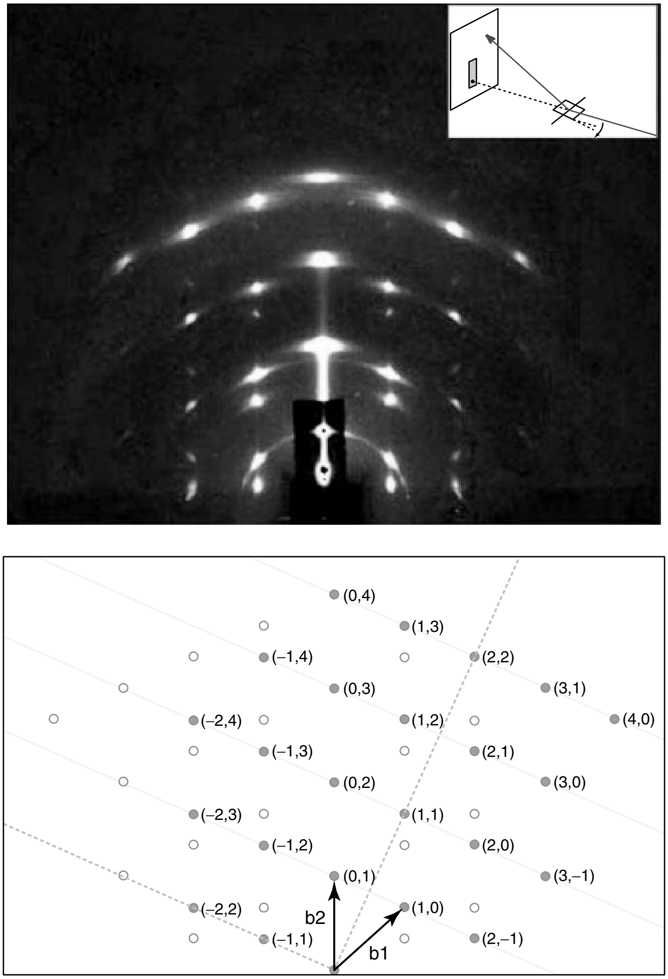

Fig. 14.24 (Top) The detector image of X-ray reflection from a 2 : 1 mixture of di18:0(9,10Br)PC and cholesterol in the $H_{II\delta}$ phase. The inset shows a schematic of the diffraction geometry. (Bottom) The diffraction pattern was translated to the reciprocal space according to the diffraction geometry. The two reciprocal vectors are $\mathbf{b}_1 = (0.1314\text{Å}^{-1} \sin 48.2^\circ, 0.1314\ \text{Å}^{-1} \cos 48.2^\circ)$ and $\mathbf{b}_2 = (0, 0.1314\ \text{Å}^{-1})$, expressed in (q_x, q_z). The angle between the two basis reciprocal vectors is 48.2°, which substantially deviates from the hexagonal angle of 60°. The solid green dots are the lattice defined by $\mathbf{b}_1$ and $\mathbf{b}_2$. The open circles are the mirror image of the lattice reflected by the mirror plane along the q_z and perpendicular to q_x – this left–right symmetry is due to the sample being a 2D powder on the plane of the substrate. Owing to the equality $|\mathbf{b}_1| = |\mathbf{b}_2|$, there are two mirror planes (purple lines) in the crystal lattice, one bisecting $\mathbf{b}_1$ and $\mathbf{b}_2$, another bisecting $-\mathbf{b}_1$ and $\mathbf{b}_2$ (Wang *et al.*, 2007). (Please find a color version of this figure on the color plates.)

components lower the free energy of the curved structure? Do the high-curvature lipid components modify the average spontaneous curvature of the relevant monolayer, thereby facilitate its bending, or do the lipid components redistribute in the curved structure so as to lower the free energy? This question is fundamental to the curvature elastic energy for lipid mixtures.

The diffraction pattern of the distorted hexagonal phase is shown in Figure 14.24, and the MAD analysis is shown in Figure 14.25. Again we used a model fitting to the Br distribution to solve the phase problem. The experimental electron density distributions of the Br atoms and the whole lipids are shown in Figure 14.26. Clearly the brominated lipids are distributed mainly in the low curvature region, leaving the high curvature region to cholesterol. Note that the lipid distribution of the same mixture is homogenous and uniform in the lamellar and hexagonal phases. But in the distorted hexagonal phase the lipid monolayer has nonuniform curvature and cholesterol almost entirely concentrates in the high curvature region. This finding demonstrates that

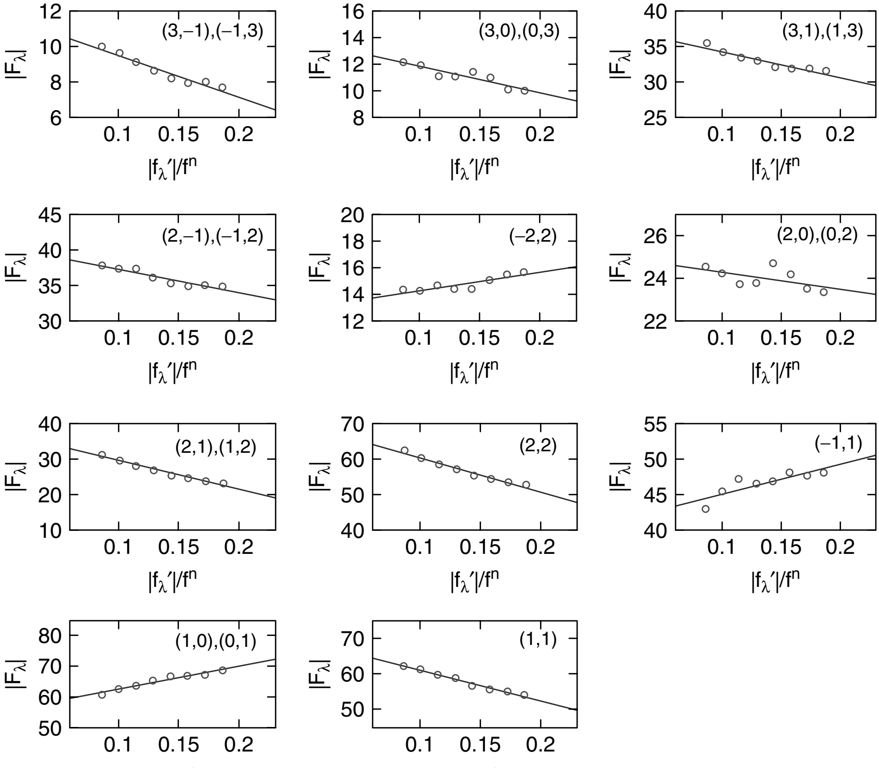

Fig. 14.25 MAD analyses for the detected peaks. For each independent peak, the square-root of the integrated intensity $|F_\lambda|$ is plotted as a function of $|f'_\lambda|/f^n$. The data are fit with a straight line, from which $|F_0|^2$, $|F_2|^2$, and the ratio F_0/F_2 are obtained (Wang *et al.*, 2007).
